3.10 SITE 35 - CAMP GEIGER AREA FUEL FARM

3.10.1 SITE BACKGROUND

Camp Geiger Area Fuel Farm (Figure 35-1) is located north of the intersection of G and Fourth Streets, approximately 400 feet southwest of Brinson Creek (PWDM Coordinates 12, Cll). This 2,500 square feet AOC was used in 1957 and 1958 for storing and pumping fuel. Mogas was released to the soil through a leak in an underground line near an above-ground storage tank and tank pad. The Camp Lejeune Fire Department has estimated the amount of fuel released to be in the thousands of gallons. Exact quantities released can not be determined since the records were destroyed. The spill migrated east and northeast towards and into Brinson Creek. Fuel at the surface of the shallow aquifer was disposed of by digging holes to the water table and igniting the fuel. Fuel which contaminated Brinson Creek was also ignited and burned.

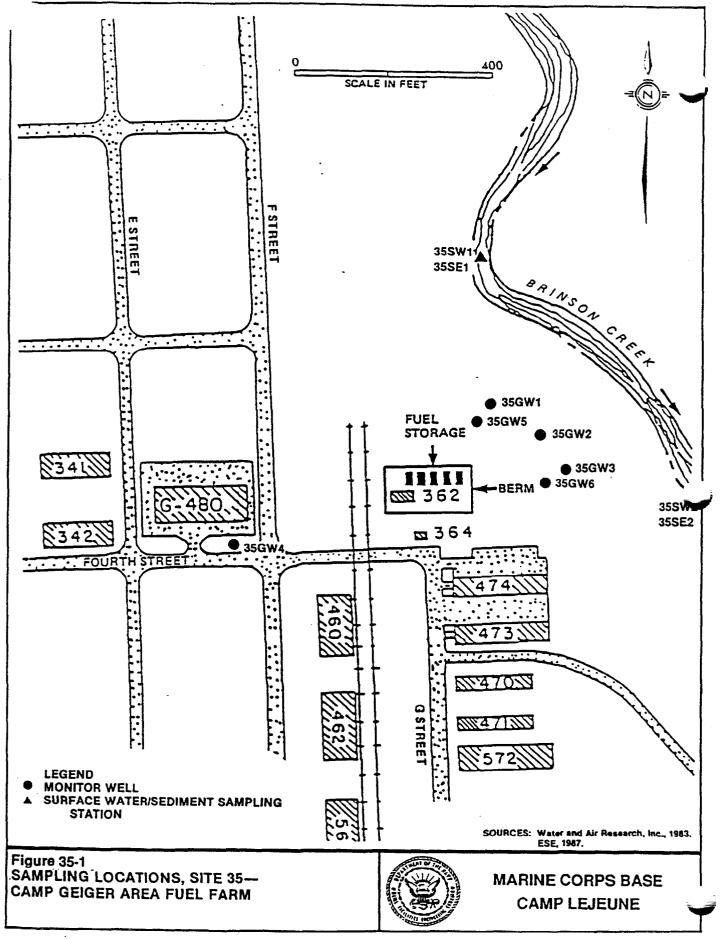

Site 35 is underlain by layers of silty sand with interbedded layers of clayey sand, coarse sand, and sandy gravel. A geologic cross section of Site 35 is presented in Figure 35-2. The cross section is drawn on an east-west line (Figure 35-3). The surface of the shallow groundwater lies within the interbedded silty sand and clayey sand at depths ranging from 7.02 to 11.05 feet below land surface. The groundwater contour map presented in Figure 35-4 indicates that the shallow groundwater flows to the northeast toward Brinson Creek with a gradient of approximately 0.014 ft/ft.

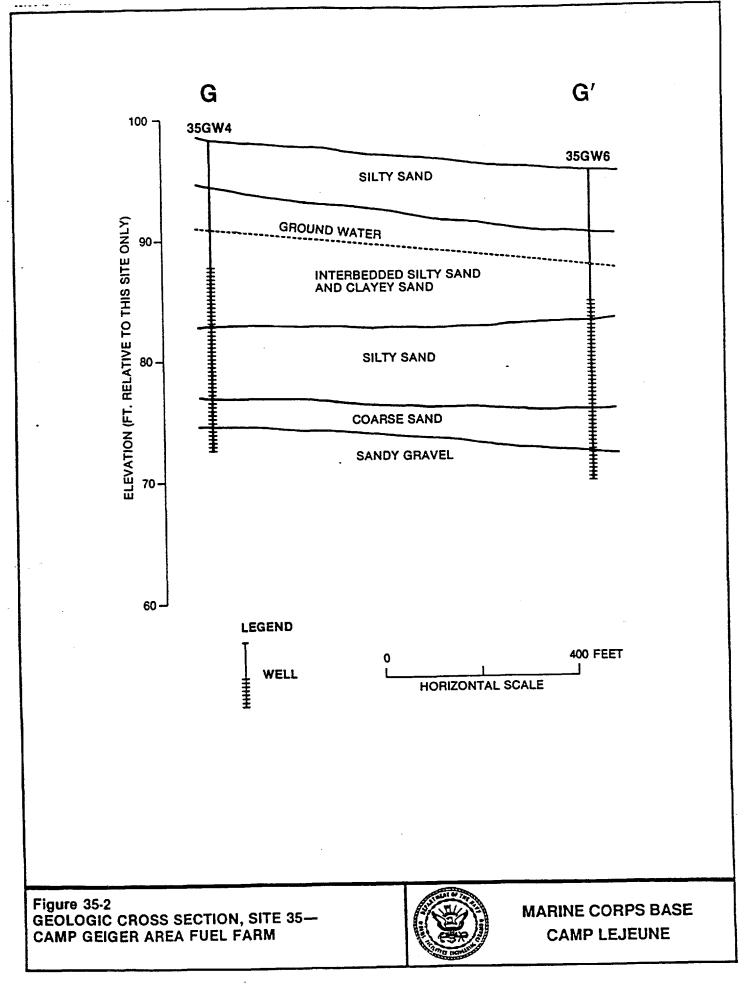

3.10.2 SITE INVESTIGATION

GROUNDWATER

Three hand-augered borings to the groundwater surface were dug at the downgradient side of the facility in 1984 and three groundwater samples were collected (35GW1, 35GW2, and 35GW3). The samples were analyzed for lead, O&G, and VOCs. Appendix A lists the individual target analytes and their abbreviations. Table 35-1 presents the analytical results for those analytes that were above the appropriate method detection limits. Levels of lead (above N.C. Groundwater Standards) were identified in all three samples which indicates that the shallow groundwater was contaminated from the release of fuel into the soils. The VOC components of the fuel were not detected.

Source: ESE, 1990.

Three permanent groundwater monitoring wells were installed in 1986 to allow for more representative samples of the groundwater (Figure 35-1). Well 35GW4 was installed upgradient of the spill area and Wells 35GW5 and 35GW6 were installed downgradient. The groundwater samples taken from these wells were analyzed for lead, O&G, and VOCs, as well as xylene and ethylene dibromide (EDB). Table 35-1 presents the analytical results of the December 1986 and March 1987 sampling efforts. In the upgradient well (35GW4), no analytes were detected except for O&G in 1986. In 1987, O&G and trans-1,2dichloroethene were detected. The source of these two analytes in the upgradient well is not clearly defined in the current database.

Wells 35GW5 and 35GW6 were found to contain sporadic distributions of fuelderived compounds and VOCs. Benzene, lead and O&G were detected in Well 35GW5, which is located northeast of the tanks. This suggests that the detected analytes are a result of the recorded fuel spillage at the site. Well 35GW6 is located east of the tanks and was found to contain O&G, trans-1,2-dichloroethene, trichloroethene and benzene. The presence of VOCs in this well suggests that widespread low level contamination of the shallow aquifer may be present as a result of the fuel release or other as yet unidentified sources. Well 35GW6 is in a generally cross gradient position of the tanks and is located approximately 200 feet downgradient of an automobile maintenance (hobby) shop. Due to the distance of the well from the tanks, VOCs in the recorded fuel release may not be a sole contributor to VOCs in the groundwater at Well 35GW6. The automobile maintenance shop represents a potential source of waste solvents detected in this well.

SOILS

Ξ

Three soil samples were analyzed from the three hand-augered borings in 1984. Lead and O&G were detected in all three samples. The analytical results are listed below.

	_	<u> Concentration (ug/g)</u>				
Parameter	3	5GW1	35GW2		<u>35GW3</u>	
Lead	8	6	j.	6		
Oil and grease		67	2200		40	

SURFACE WATER

Two surface water samples were collected from Brinson Creek in 1986, one upstream and one downstream of the site (Figure 35-1). These samples were analyzed for lead, O&G, and ethylene dibromide. No target analytes were detected in either sample.

SEDIMENT

Two sediment samples from Brinson Creek were taken in 1986 at the same locations as the surface water samples. These samples were analyzed for lead, O&G, and ethylene dibromide. Both sediment samples were found to contain lead and O&G, suggesting that episodic contamination of the creek has occurred or is occurring. Levels of both these analytes were higher in the upstream sample, suggesting that the discharge of contaminated groundwater to the creek is occurring at the far northern section of site and that the sample was not taken far enough upstream to truly represent upstream conditions. Another possibility is that the source of O&G and lead may be located upstream of Site 35.

3.10.3 SUMMARY AND CONCLUSIONS

The 1986/87 analytical data indicate that widespread contamination of the shallow aquifer with fuel derived contaminants and VOCs may exist at Site 35. The migration mechanisms by which contaminants have migrated to the upgradient well have not been identified. However, due to the nature of hydrocarbon fuel, a spill would tend to widely disperse on the surface of

3-101

groundwater in a sandy medium. This would explain the concentrations of fuel related compounds in Well 35GW4. A second separate source of observed contaminants may be present at the automobile maintenance shop located upgradient of Well 35GW6.

The groundwater contour map (Figure 35-4) indicates that groundwater flow is towards Brinson Creek. Surface water samples contained no detectable target analytes. Sediment samples, however, contained lead and O&G. Because at the time of the fuel release to the environment, fuel reached the creek, it can be assumed that contaminants may be currently discharging to the creek via the groundwater.

3.10.4 RECOMMENDATIONS

The work efforts to date at this AOC have identified the presence of fuel derived contamination in the soils, shallow groundwater, surface water, and sediments. Further investigations should be designed to determine the extent (horizontal and vertical) of the contamination within the soils and groundwater and within Brinson Creek. In addition, investigation of the adjacent automobile hobby shop should be initiated to determine if that facility is a source of VOC contamination. A Risk Assessment should be conducted upon completion of the environmental characterization.

1

1.1 <u>Purpose of Investigation</u>

On September 29, 1990, the Commander of the Atlantic Division Naval Facilities Engineering Command (LANTDIV) in Norfolk, Virginia, contracted with Law Companies Group, Inc. to perform a Comprehensive Site Assessment (CSA) at the Camp Geiger Fuel Farm, Marine Corps Base (MCB), Camp Lejeune, North Carolina (Drawing 1.1). The purpose of the investigation was 1) to identify the presence, magnitude and extent of possible free-product accumulation and ground-water contamination and 2) to assess potential exposure to subsurface contaminants resulting from the release(s) of petroleum fuels. As stated in the CSA Workplan contained in Appendix A, the objective of the investigation was to provide sufficient data to meet the requirements of Sections 280.63 and 280.65 of 40 CFR Part 280, Federal Technical Standards for Underground Storage Tanks. This data should also be sufficient to meet the requirements of Sections .0704 and .0706 of Title 15A, Chapter 2, Subchapter 2N, North Carolina Criteria and Standards Applicable to Underground Storage Tanks.

1.2 <u>Scope of Work</u>

Authorization to proceed with the investigation was granted by the Commander of LANTDIV of Norfolk, Virginia, via Contract/Purchase Order No. N62470-90-D-7625/0002 dated September 29, 1990.

As outlined in the contract and the CSA Workplan, the Scope of Work included preparation of a health and safety plan, collection of ground-water samples using the Hydropunch ground-water sampling system, performance of a soil-gas survey and tracer testing of the underground fuel lines, excavation of soil borings, installation of monitoring wells, collection and analysis of soil and ground-water samples, performance of a preliminary exposure assessment, performance of a preliminary evaluation of remedial alternatives, preparation of a final report of investigation and presentation of data and conclusions. Specific methods employed during performance of the project activities are described within the appropriate sections of this report.

1.3 <u>Previous Investigations</u>

A leaking underground line was reportedly discovered at the Camp Geiger Fuel Farm (Fuel Farm) in 1957-58. Law Engineering could not locate written documentation of

this incident, but found reference to it in a report by Environmental Science & Engineering (ESE) of Plymouth Meeting, Pennsylvania (1990). This report stated that the Camp Lejeune Fire Department estimated that thousands of gallons of fuel was released; the records documenting the exact quantities of the spill have been destroyed. The spill migrated to the east and northeast into Brinson Creek. Gasoline at the top of the surficial aquifer was exposed by digging trenches; the fuel was then ignited and burned. Fuel which reached Brinson Creek was also ignited and burned. Mr. Ron Waters of Direct Support Stock Control of the Logistics Department at Camp Geiger, who has been employed at Camp Geiger for 35 years, stated that a fireman from the Camp Geiger Fire Department had told him that the leak occurred when a dispensing pump was damaged. He was also told that the Fire Chief had to wade through the spilled product to turn off the valve to the pump.

MCB Camp Lejeune is listed on the National Priority List (NPL) and Wastelan Preremedial Report, both of which are compiled by the Environmental Protection Agency (EPA) and monitored by the Division of Solid Waste Management of the North Carolina Department of Environment, Health and Natural Resources. MCB Camp Lejeune was placed on the NPL in 1983, after Water and Air Research, Inc. of Gainesville, Florida performed an Initial Assessment Study of 76 potentiallycontaminated sites at the base. Water and Air Research identified 21 of these sites

I

as warranting further investigation. Camp Geiger Fuel Farm is one of the 21 sites recommended for further investigation. A twenty-second site at Camp Lejeune was later added to this list.

ESE performed Confirmation Studies of the 22 sites requiring further investigation and performed the Fuel Farm study between 1984 and 1987 (ESE, 1990). During this study, ESE advanced three hand-auger borings, collected ground-water and soil samples from each and documented ground water contaminated with lead and soil contaminated with lead, oil and grease. In 1986, ESE collected sediment and surfacewater samples from Brinson Creek and installed three monitoring wells, two east of and one west of the Fuel Farm. These wells were sampled after installation and again in 1987. Laboratory analysis did not reveal surface-water contamination, but did document lead, oil and grease in the sediment and soil samples. Ground water from both the upgradient and downgradient wells was found to be contaminated with volatile organic compounds. ESE could not identify a source for the contamination documented in the upgradient well. ESE identified two possible sources for the contamination in the downgradient wells. The first was the fuel spill which occurred at the fuel farm in the 1950's and the second was an automotive maintenance shop located southeast to the Fuel Farm, in Building No. TC-474.

NUS Corporation performed an investigation in the area north of the Fuel Farm in 1990. According to the NUS report (NUS, 199●), fuel was observed in a stormwater drainage ditch. Base personnel constructed an earthen dam in the drainage ditch to contain the fuel and rerouted storm drainage to the south. NUS installed four monitoring wells, three in the vicinity of the ponded stormwater and one in an apparent upgradient position. Results of laboratory tests performed by NUS revealed that ground water in one well and soil from the cuttings of two soil borings in the vicinity of this drainage ditch were contaminated with petroleum-fuel constituents. No free-phase petroleum hydrocarbons (free product) were reportedly observed in the wells. Ms. Amy Hubbard, project manager of the investigation for NUS, stated that NUS personnel did not observe any free product over the 8-week period of their investigation. Ms. Hubbard stated that she believes that the contamination resulted from a one-time surface release of product. Ms. Stephanie del Re-Johnson of the Installation/Restoration Division of the Environmental Management Department (EMD) at Camp Lejeune stated that she had observed a 5-foot thickness of free product on the surface of the ponded water. NUS determined from the four monitoring wells that the local direction of ground-water flow was to the northeast.

)

I

During their investigation, NUS also conducted a geophysical survey in an attempt to determine if underground storage tanks (USTs) remained at the site of the former

gasoline station. This gasoline station was located west of the Fuel Farm and south of the headwaters of the drainage ditch in which the fuel was discovered. From the data acquired during this geophysical survey, NUS identified an anomaly to the north of the foundation of the gasoline station.

In addition to the ESE and NUS assessments, the United States Geological Survey (USGS) performed an investigation at MCB Camp Lejeune (Harned et al, 1989). This study is referenced fully in Section 8.0 of this report and includes discussions of the hydrology and hydrogeology of Camp Lejeune.

2.0 DESCRIPTION OF SITE

1

2.1 Area of Investigation

The Camp Geiger Fuel Farm is located on the north side of Fourth Street at its intersection with G Street at Camp Geiger, Camp Lejeune MCB, Onslow County, North Carolina (Drawing 1.1). The site is situated entirely within the confines of Camp Geiger. The study area is bounded on the west by D Street, on the north by Second Street, on the east by Brinson Creek, and on the south by Building No. TC-474

(Drawing 2.1). Mr. Tom Morris of the Installation/Restoration Division of the EMD and Mr. John Starcalla of the Public Works Department at Camp Lejeune provided numerous site drawings showing the locations of underground utilities and aboveground structures. We have included a list of these drawings in Table 2.1.

2.2 <u>History and Operations of the Site</u>

2.2.1 History of the Site

]

1

Ţ

Construction of Camp Lejeune began in 1941. Construction of Camp Geiger was completed in 1945. We have not been able to identify when Camp Geiger Fuel Farm was constructed, although we have reviewed a site plan for the Fuel Farm which is dated July 17, 1941 (Y. and D. Drawing No. 161783). When constructed, the tanks at the Fuel Farm were used for the storage of No. 6 fuel oil. The tanks were converted for storage of other petroleum products when No. 6 fuel was no longer needed. Law Engineering could not determine when this conversion occurred.

Law Engineering has identified three sites in the study area which once were the sites of structures which have since been demolished. The first site is an ice house, which was located adjacent to the railroad spur on the west side of the Fuel Farm. The ice

house was supplied with ice brought to the site by train. Mr. Morris provided drawings of the ice house (Building No. TC-360, Y. & D. Drawing Nos. 161813 and 161814, dated June 26, 1941). The site drawing does not show underground utilities other than water and water drains. We cannot determine when the ice house was demolished. The foundation and pilings which supported the ice house remain at the site.

The second site is a "filling" (gasoline) station, which was located on the northeast corner of the intersection of F and Fourth Streets, adjacent to the ice-house site. Mr. Morris provided a site drawing of the building which had occupied the site (Building No. 341, P.W. Drawing No. 2816, dated November 12, 1947) but could not locate a site plan showing the location of the storage tanks, distribution lines and dispensing pumps. We cannot determine when the filling station was demolished. The foundation to the filling station remains at the site.

The third site is a mess hall, with an associated boiler and underground storage tank (UST), which was located adjacent to D Street, between Third and Fourth Streets. Mr. Morris provided a drawing (Y. and D. Drawing No. 161873) showing the location of an underground fuel distribution line, which extended from the Fuel Farm to the UST, and the approximate location of the UST. Mr. Morris stated that this UST stored

No. 6 fuel oil when the boiler was in operation. We cannot determine when the mess hall was demolished, although Mr. Morris stated that he believed this occurred in the 1960's.

In Building No. TC-474, south of the Fuel Farm, Law Engineering understands that automotive maintenance was performed until approximately 4 years ago. Although this building is outside of the study area, activities undertaken there may have had an environmental impact on the area around the Fuel Farm.

]

]

]

Mr. Anthony Koonce, civilian-in-charge of fuel dispensing at the fuel farm, discussed with Law Engineering an incident which occurred approximately 4 years ago. Mr. Koonce stated that daily inventory-control records at the Fuel Farm were out of balance by approximately 30 gallons per day. After review, this imbalance was attributed to a leak in the gasoline line which carried gasoline from the pump house to the dispensing island. This line was sealed off at both ends and replaced by a line which runs along the eastern side of the Fuel Farm. A subsurface investigation was not undertaken at the time of the possible release to document soil or ground-water contamination which may have resulted from this leak.

Law Engineering identified a UST located behind and adjacent to Building TC-480 which was installed in 1976. This UST has a capacity of 550 gallons and contains #2 fuel oil, which is used to heat Building TC-480.

2.2.2 Operations of the Site

]

]

The Fuel Farm contains aboveground storage tanks (ASTs) which are used to dispense gasoline, diesel and kerosene to government vehicles and to supply USTs in use at Camp Geiger and the Air Station. These ASTs are refilled by trucks which are operated by commercial carrier and which deliver product to fill ports at the southern end of the storage facility. The operation of the Fuel Farm is supervised by two attendants who operate the facility from a small building (Building No. TC-364, Drawing 2.2) at the southern end of the Fuel Farm. There are five ASTs at the Fuel Farm:

- two diesel fuel ASTs, each with a capacity of 15,000 gallons,
- two unleaded gasoline ASTs, each with a capacity of 15,000 gallons, and

one kerosene AST with a capacity of 15,000 gallons.

According to the site drawing referenced in Section 2.2.1, the initial tanks were placed in service in the early 1940's. Mr. Waters stated that the original tanks have never been replaced.

There are six underground lines used to distribute fuel within the fuel farm (Drawing 2.3). These are:

- an unleaded gasoline line approximately 70 feet long which connects the fill port and pump house;
- an unleaded gasoline line approximately 140 feet long which connects the pump house and vehicle dispensing pump;
- a diesel line approximately 70 feet long which connects the fill port and pump house;

- a diesel line approximately 120 feet long which connects the pump house and both the overhead dispensing pump and the vehicledispensing pump on the pump island;
- a kerosene line approximately 80 feet long which connects the fill port and pump house; and
- a kerosene line approximately 110 feet long which connects the pump house and the overhead dispensing pump.

The underground lines now in place are those originally installed, with the exception of the recently-installed gasoline line referenced in Section 2.2.1. Mr. Koonce stated that their standard operating procedures include performing daily inventory-control procedures.

There are also three underground lines at the Fuel Farm which are no longer used and which have been sealed off. These three abandoned lines are:

 a gasoline line approximately 60 feet long which connected an abandoned fill port and the pump house;

- a diesel line approximately 20 feet long which connected an abandoned fill port and the pump house; and
- a gasoline line approximately 120 feet long which connected the pump house and pump island.

Law Engineering has found evidence that there also may be one additional line connecting the Fuel Farm and an underground storage tank (UST). The path of this line is shown on Drawing No. 2.4. As indicated in Section 2.2.1, this line carried No. 6 fuel oil from the Fuel Farm to a UST which may still be located at the site of a former mess hall. Law Engineering could not determine if this line was removed when the UST was abandoned.

2.3 Inventory of Contaminant Sources

](

USTs identified in and around the Fuel Farm are listed in Table 2.2. The location of USTs with respect to the site are presented in Drawing 2.5. Please note that Table 2.2 includes only those tanks that have been identified during the course of this investigation. The possibility remains, however, that other unidentified USTs are present near or were in the past located near the Camp Geiger Fuel Farm.

In addition to the USTs listed in Table 2.2, nine active and inactive product transmission lines are or have been located in the study area, as identified in Section 2.2.2. These product lines are also presented in Drawing 2.5.

2.4 Inventory of Water Wells

As part of our survey to identify potential receptors of ground-water contaminants, Law Engineering performed a survey of drinking-water wells in the vicinity of Camp Geiger Fuel Farm by reviewing USGS Report 89-4096 and through discussions with Mr. Morris. This report shows the locations of drinking-water wells in Camp Geiger, all of which are located adjacent to A Street and over 2000 feet west of the Fuel Farm (Drawing 2.6). Our survey of wells targeted those located within one-half mile of the project site in order to provide an adequate area of coverage. A discussion of the results of the survey of potential receptors is provided in Section 6.0 of this report.

We have presented a summary of the well inventory in Table 2.3, which provides information on the well depth, casing diameter, well usage and the well's approximate distance from the Fuel Farm. Each of the wells identified was constructed as an openhole wells in the Castle Hayne Aquifer. The Castle Hayne aquifer and the hydrogeology of the area are introduced and referenced in Section 3.0 of this report.

2.5 <u>Survey of Underground Utilities</u>

1

]1

}

1

]].__

]|

Subsurface utility trenches can often provide preferential pathways for migration of contaminants. Therefore, Law Engineering attempted to identify and locate subsurface utilities in the vicinity of Camp Geiger Fuel Farm. Mr. Morris provided plans and drawings showing the locations of subsurface utilities, the locations of which are shown in Drawings 2.7, 2.8 and 2.9. Typically, underground utility lines are buried 2 to 6 feet below land surface (bls). As previously indicated, underground fuel transmission lines are exhibited in Drawing 2.5.

3.0 SITE HYDROGEOLOGIC CHARACTERIZATION

3.1 <u>Site Topography</u>

As indicated by the Jacksonville South, N.C. topographic quadrangle, published by the United States Geological Survey in 1952 and photorevised in 1971 (Drawing 1.1), the elevation of land surface in the vicinity of Camp Geiger Fuel Farm generally ranges from 3 to 17 feet above mean sea level (msl) and the land surface slopes toward the northeast. Most of the study area is not serviced by storm sewers, and runoff

generally travels by sheet flow before entering natural drainage ditches which discharge into Brinson Creek, to the east and northeast of the study area.

3.2 <u>Regional Geology/Hydrogeology</u>

The study area is located within the Lower Coastal Plain Soil System (Wiscomico and Talbot System) and the Coastal Plain/Castle Hayne Limestone hydrologic area. A brief summary of the geologic/hydrogeologic setting at the Camp Geiger Fuel Farm is provided in Section 2.2 of the CSA Workplan (Appendix A). In general, downward movement of ground water is obstructed by the presence of clay layers in Coastal Plain formations and consequently most of the ground-water recharge migrates laterally toward discharge areas through the surficial aquifer (Heath, 1980). Further details of regional geologic/hydrogeologic characteristics are provided in the USGS Water-Resources Investigation previously cited (Harned 1989).

3.3 Site Soils and Geology

1

Law Engineering performed field activities on August 15-30, 1991, which consisted of the following:

Advancing 18 soil borings, which were subsequently used for the installation of monitoring wells;

]]-

]|

]|

]

÷ : •

- Advancing 5 soil borings to check for the presence of soil contamination;
- Advancing 3 stratigraphic borings to determine the geology of the subsurface in the study area; and
- Advancing 9 shallow hand-auger borings to check for the presence of soil contamination in suspect areas.

The locations of these borings are shown on Drawing 3.1. We were unable to complete boring B-3 as planned. We attempted this boring six times and each time encountered auger refusal due to steel reinforcing wire in the concrete pad or unidentified obstructions just below the pad.

Law Engineering accomplished all drilling using hollow-stem augers and techniques described in ASTM D-1452. We steam-cleaned our down-hole drilling equipment prior to work at each drilling location. We used augers with an inside diameter of either

3.25 or 3.75 inches for the drilling of a "pilot" hole and for the collection of soil samples. After completing the "pilot" hole, we reentered each monitoring-well borehole using augers with an inside diameter of 8.25 inches to allow the placement of two sets of PVC pipe in the well. We grouted to land surface those soil borings not used for the installation of monitoring wells.

Site geologists collected soil samples from each of the soil borings for field classification, headspace testing and chemical testing. We generally obtained soil samples for field classification at depths of 0 to 1.5 feet, 1.5 to 3 feet, 3 to 4.5 feet and on 5-foot centers thereafter to boring termination. We collected these soil samples with a split-spoon sampler 24 inches long and with an inside diameter of 1.375 inches (outside diameter of 2 inches). We obtained each soil sample by repeatedly allowing a 140-pound hammer to fall free for 30 inches, until the sampler was driven 18 inches into the substrate. We performed split-spoon sampling in general accordance with ASTM D-1586 and recorded on the field boring log the number of blows required to drive the sampler each 6-inch increment. After donning laboratory-grade gloves, we placed representative portions of each sample in two, pre-labeled plastic bags and sealed each bag for subsequent headspace testing.

Site geologists examined in the field the soil collected at each interval using visual/manual techniques described in ASTM D-2487 and ASTM D-2488 and classified the soil in general accordance with the United Soil Classification System. We have included a record of each test boring in Appendix B.

ļ

]|

The soil and stratigraphic borings penetrated three distinctive units. The first unit is a fine- to medium-grained, unconsolidated sand. The thickness of this unit ranges from 15 to 30 feet. Law Engineering selected two samples of this unit to be analyzed for grain-size distribution, the results of which are presented in Appendix C. We performed these analyses on samples from MW-23, collected from a depth of 8.5 to 10.5 feet, and from MW-24, collected from a depth of 13.5 to 15.5 feet. These analyses revealed that the samples generally contain 96% sand and 4% silt and clay.

The second unit is a oolitic, fossiliferous limestone which ranges in thickness from 6.5 to 20 feet. The fossils consist of fragments of mollusks; the matrix consists of finegrained sand, fine-grained phosphate grains and lime mud. Under the Folk classification (Blatt et al, 1972), this unit is a biosparite. Mr. Rick Shiver of the Wilmington Regional Office of the DEM stated that this unit is common in the Jacksonville area and is considered part of the unconfined, surficial aquifer. Law Engineering believes this unit is the River Bend Formation.

The third unit is an unconsolidated, dark gray to black silty, clayey sand. Because this unit may be a confining unit separating the surficial and Castle Hayne aquifers, Law Engineering did not attempt to completely penetrate this clayey sand, and therefore, the thickness is not known. We sampled this unit in SB-1, SB-2, SB-3 and MW-19 and observed this unit up to 4 feet thick in SB-2. Law Engineering selected the sample of this unit from SB-1 to be analyzed for grain-size distribution, the results of which are presented in Appendix C. This analysis revealed that the sample contained 79% fine sand, 9% silt and 12% clay.

This clayey sand is probably the same described by Harned et al (1989) as one of many occurring in the surficial aquifer and the Castle Hayne. These units are reportedly not confining units in the Camp Lejeune area because the units are thin and discontinuous. This report noted, however, that the units appears to be thicker and more continuous in the northwestern part of Camp Lejeune, where the Fuel Farm is located. Law Engineering believes that this clayey sand acts as a confining unit in the study area due to its relatively high percentage of silt and clay. We believe that this unit separates the surficial aquifer from the underlying Castle Hayne aquifer.

Law Engineering developed two cross sections from soil-boring records in order to facilitate lithologic interpretation. The locations of these cross sections are exhibited

4

in Drawing 3.2; the cross sections are illustrated in Drawings 3.3 and 3.4. As shown in the cross sections, the stratigraphic units encountered within the surficial aquifer consist of the unconsolidated sand, lithified limestone (River Bend Formation) and clayey sand. Law Engineering believes that the upper contact of the River Bend Formation is not a planar surface and we expect its thickness to be highly variable. We observed this variability in SB-3 and MW-19. While only 240 feet apart, the thickness of the River Bend in SB-3 is 20 feet and the thickness in MW-19 is 6.5 feet.

3.4 <u>Site Hydrogeology</u>

Law Engineering installed a total of 18 ground-water monitoring wells, utilizing the materials and installation procedures described in the CSA Workplan. In order to monitor ground water at multiple depths and delineate the vertical extent of ground-water contamination at the Fuel Farm, we installed "paired" monitoring wells in 17 of 18 boreholes, each with a "shallow" screened interval and a "deep" screened interval. There is one well (MW-20) that is not paired; we encountered auger refusal with the large-diameter augers at the top of the River Bend Formation and therefore were not able to set a deep screen. Installing paired wells allowed us to sample the ground water at the water table and at depths of 10 to 20 feet below the water table, thus enabling us to investigate the vertical extent of contamination.

The specifications for each soil boring included decontaminating the drilling equipment and well construction materials with a pressurized steam-cleaning unit, emplacing a silica-sand filter pack and a bentonite seal above the filter pack, grouting the well above the bentonite seal with a cement/bentonite slurry, and developing the well through low-yield pumping. In Tables 3.1 and 3.2, we have listed the approximate volumes of water removed during well development and our observations of turbidity of the development water.

The wells constructed by Law Engineering are protected by a lockable, stick-up cover constructed of steel. This stick-up cover is embedded in a concrete pad and is protected by three steel bollards filled with concrete. Details for the installation of the monitoring wells are included in Appendix D.

During the period September 3-5, 1991, Law Engineering measured depths to ground water in all monitoring wells, the results of which are listed on the Monitoring-well Casing and Water-elevation Worksheets in Appendix E. Elevations of all measuring points were reviewed and certified by a Registered Land Surveyor; these points are also listed in these worksheets.

4

Based on ground-water elevations measured in the "shallow" monitoring well of each well pair and several of the pre-existing wells, we prepared a water-table contour map, from which we determined the direction of ground-water flow (Drawing 3.5). Ground water in the surficial aquifer generally flows across the project site to the east. towards Brinson Creek. As indicated by comparing water level elevations recorded on September 3, 1991 between "shallow" and "deep" screened intervals, ground water in the surficial aquifer generally moves laterally across the project site with no significant vertical gradient. However, we observed a slight vertical component of upward movement in MW-23 and MW-25, both of which are located near natural discharge points -- Brinson Creek and the intermittent streams which discharge into At these locations we would normally expect some upward Brinson Creek. component of ground-water flow as ground water seeks to discharge into surface drainage features. We did not use the ground-water elevations measured in EMW-6 and EMW-7 because these wells are screened below the water table and the elevations were inconsistent with measurements obtained from nearby wells. Likewise, we did not use the ground-water elevation measured in MW-24 because the measurement was so dissimilar from nearby wells. Law Engineering cannot determine the reason for this dissimilarity.

Ĵ

The rate or average linear velocity of ground-water movement across the project site is a function of the hydraulic conductivity (K) of the aquifer medium, the effective porosity (n) of the aquifer medium and the hydraulic gradient (dh/dl) that exists in the surficial aquifer. We calculated the hydraulic conductivity of the unconsolidated sands in the surficial aquifer at the study area based on results of previous studies performed on unconsolidated sands by F.D. Masch and K.J. Denny (in Freeze and Cherry, 1979). We used the data in the grain-size gradation curves (Appendix C) in these calculations for the samples from MW-23 and MW-24. Based on the results of the calculations, we expect the hydraulic conductivity of the unconsolidated sands within the surficial aquifer to be approximately 28 feet/day (Appendix C). Based on the recharge rate of the wells screened over this unit and a review of hydraulic conductivity estimates published by Freeze and Cherry (1979), we expect that the hydraulic conductivity of the River Bend is at least as great as that of the unconsolidated sand.

We calculated the average, linear velocity of ground-water flow in the unconsolidated sands within the surficial aquifer, using the computer program Water-Vel (1989). This program allows us to predict the general direction and average, linear velocity of ground-water flow based on three values: piezometric (water-table elevation) measurements, calculated value of hydraulic conductivity, and estimated values for effective porosity. Water-Vel calculations are based on Darcy's Law (q = K [dh/dl])

and the relationship between Darcy velocity (q) and average, linear, velocity of ground water (v = q/n).

Using Water-Vel, we calculated a range of average, linear velocities of between 0.99 feet/day (n = 25%) and 1.66 feet/day (n = 15%) using values for effective porosity of 15% to 25% for fine sand, as estimated by Walton (1984). These calculations are included in Appendix F. The values for effective porosity are an estimate and are based on the predominant soil types encountered during construction of borings at the project site. Please note that this calculated velocity is an average velocity across the entire project site; the actual rate at a specific location at the site may be more or less than the rate calculated herein.

4.0 ASSESSMENT OF SUBSURFACE CONTAMINATION

4.1 <u>Tracer Tight Leak Testing</u>

Law Engineering subcontracted with Tracer Research Corporation of Tucson, Arizona to perform a tracer test of the underground fuel lines within the Fuel Farm, the report of which is included as Appendix G. This test was accomplished by adding a highlyvolatile liquid tracer to the fuel in the fuel system and allowing approximately two

weeks for the tracer to become distributed throughout the system. On August 19, 1991, personnel from Tracer Research and Law Engineering installed 29 soil-gas probes along the underground fuel transmission lines at the fuel Farm (Drawing 4.1) to detect tracer gas that may have been released to the surrounding soil.

Tracer gas was not detected in samples collected by the probes. Based on this result, Tracer determined that the tank and pipe systems that were tested at the Fuel Farm passed the precision leak test, which is capable of detecting leaks of 0.05 gallons per hour with a probability of detection of 0.97 and a probability of false alarm of 0.029. However, samples collected by the probes did contain volatile hydrocarbons in three locations, as shown in Figure 2 of the Tracer study. The largest vapor "plume" occurs below the fuel-loading pad and may have resulted from the contamination from the leaking gasoline line referenced in Section 2.2.1. There are two smaller plumes under the fuel tanks which may have resulted from surface spills. We used the results of this study to determine locations of soil borings B-2 and B-3 and hand-auger borings HA-3 and HA-4, which are located in two of the three plumes identified in the Tracer study.

4.2 Soil Contamination

4.2.1 Scanning Procedures

Law Engineering monitored all soil-investigation activities with a photoionization detector (PID) manufactured by HNu Systems (Model PI 101) which had been calibrated to isobutylene. We used the PID to qualitatively measure total volatile organics in the borehole, in ambient air, and in the individual soil samples. Values recorded with the PID are qualitative only and are not directly comparable to actual laboratory analytical results. However, the PID is useful in providing a relative indication of the presence of volatile organics in soil samples.

4.2.2 Hand-auger Borings

71

Law Engineering advanced hand-auger borings, each to a depth of 5 feet, to accomplish two objectives. The first objective was to check for the presence of USTs in the vicinity of the geophysical anomaly identified during the ESE investigation (Drawing 3.1) at the site of the former gasoline station. We advanced 16 hand-auger borings in this area but did not detect evidence of USTs or soil contamination by volatile organics.

The second objective of the hand-auger borings was to check for the presence of soil contamination and USTs in suspect areas. We performed these borings in four areas (Drawing 3.1). In the first area, we advanced hand-auger borings HA-1 and HA-2 where we suspected the presence of the UST associated with the former mess-hall operations. HA-1 encountered auger refusal at a depth of approximately 2 feet, which may have been due to the presence of this UST. HA-2 was advanced approximately 10 feet east of HA-1 and encountered soils with anomalous PID readings. Based on these readings, we drilled boring B-4 to check for soil contamination.

In the second area of hand-auger borings, we advanced HA-3 and HA-4 near the pump house where we identified data anomalies in the soil-gas survey. We collected soil samples for laboratory analysis from each of these borings.

In the third area of hand-auger borings, we advanced HA-5 and HA-6 behind the gasoline station and to the west of the 16 hand-auger borings, in a location where Mr. Morris had suggested that a UST may remain. We observed no indication of USTs or soil contamination in either of these borings.

In the fourth area of hand-auger borings, we advanced HA-7, HA-8 and HA-9 near where the fuel line extending from the Fuel Farm to the mess-hall UST makes a 90°

turn to the west (Drawing 4.2). We chose this location because it was in the vicinity of the contaminant plume identified by the Hydropunch sampling and because pipe joints are particularly susceptible to leakage. We collected one soil sample from HA-7 based on PID readings.

4.2.3 Soil Borings

Locations of the soil borings (B-1 through B-6, SB-1 through SB-3) and wells constructed from soil borings (MW-8 through MW-25) are shown in Drawing 3.1. Depths of the soil-test borings ranged from 15 to 44.5 feet. Moist soil conditions were generally encountered at a depth of 8 to 10 feet bls. None of the soil borings penetrated the Castle Hayne Formation, which supplies drinking water for Camp Lejeune.

We collected soil samples from each boring for headspace testing and laboratory chemical analysis according to the following procedure:

• The decontaminated split-spoon sampler was driven to the desired depth interval.

- The split-spoon sampler was retrieved and immediately opened. Portions of sample aliquots were quickly removed from the split-spoon sampler and placed into two, pre-labeled, airtight plastic bags. Sample handling was executed carefully in an effort to reduce the loss of the volatile organics. The bags were sealed and placed in a warm location.
- After approximately 10 minutes, the headspace gas in one of the two bags was tested with the PID and the peak value was recorded. This procedure was conducted for the soil sample collected at each sample-depth interval.

7

1

From the soil samples collected from the borings, the two samples that exhibited the highest PID reading were targeted for chemical analysis. For those samples, the paired sample was transferred to a laboratory-supplied glass container, placed into a cooler, packed on ice and shipped to the laboratory for chemical analysis. Law Engineering maintained custody of the samples until shipment at the end of each day.

4.2.4 Results of the Soil Sampling

<u>}</u>:

1

J

A summary of headspace analyses are presented in Table 4.1. Results show that volatile organics were detected in samples collected from 19 of the 24 boreholes. In general, concentrations of contamination were greatest in the samples collected at depths of 8.5 to 10 feet, near or just below the water table. Therefore, we suspect that lateral movement of the dissolved-phase plume and seasonal fluctuations of the water table has resulted in adsorbed-hydrocarbon contamination in the capillary-fringe area.

A summary of the results of laboratory analyses of the soil samples are presented in Table 4.2. The laboratory analyses are included in Appendix H. The soil samples were tested for total petroleum hydrocarbons (TPH) using EPA Methods 3550 (semivolatile) and 5030 (volatile) and for lead using EPA Method 6010. We also analyzed 10 soil samples for ignitability using EPA Method 1010. Although the headspace testing indicated the presence of volatile organics in a majority of the boreholes, laboratory testing for total petroleum hydrocarbons (TPH) indicated the presence of primarily high-boiling-point hydrocarbons in samples from 13 of the boreholes. We have combined the measured values of both high- and low-boiling-point hydrocarbons from samples collected above the water table and presented these data in an isopleth

map of total petroleum hydrocarbons (Drawing 4.3). This map illustrates three areas of soil contamination, all of which correlate to areas of known or suspected USTs or transmission lines. These areas are:

- the vicinity of boring no. B-4, which was installed near the location of the UST adjacent to the site of the former mess hall;
- the vicinity of the UST behind Building No. 480 and extending to the northeast towards the ponded stormwater (the area of contamination documented in the NUS report); and
 - the AST and fuel-dispensing area of the Fuel Farm, in support of the results of the tracer testing discussed in Section 4.1 and in concurrence with the verbal report of the 4-year-old release of gasoline. However, soil contamination in this area appears to be concentrated at depths below the water table.

Based on this data, it appears that there have been releases of fuel in at least three separate locations within the study area. The plume of contamination originating behind Building No. 480 may have resulted from two releases, one from the UST

system at Building No. 480 and one from a possible surface release, northeast of that site, which was investigated by NUS (Section 1.3). The pattern of soil contamination corresponds with the direction of ground-water flow. Therefore, it appears that petroleum fuel was released at these source locations and subsequently migrated through the soil towards Brinson Creek partly as a free-phase liquid hydrocarbon prior to dispersion, adsorption and dissolution into the ground water.

Law Engineering also analyzed each soil sample for lead. There was one sample (HA-4) which exhibited concentrations of lead in excess of the laboratory detection limit. This sample was collected from a location adjacent to the pump house. Because this sample was not contaminated with petroleum hydrocarbons, it appears that this lead did not originate from a discharge of leaded fuel.

Law Engineering also analyzed 10 soil samples for ignitibility. Based on the laboratory results, we determined that the flashpoint of each of the ten samples is in excess of 200°F.

4.3 Occurrence of Free Product

The monitoring wells were constructed to allow for detection of free product in the capillary-fringe area. As indicated on the Monitoring-well Casing and Water-elevation Worksheets (Appendix E), we did not detect free product using probe measurement in the wells. Therefore, Law Engineering has no evidence to indicate that free product remains in the subsurface in the study area. However, our experience reveals that, given ample time, free product can accumulate in wells which initially showed no signs of free product.

4.4 <u>Dissolved Ground-Water Contamination</u>

4.4.1 Hydropunch Ground-water Sampling

From August 5-7, 1991, as the initial phase of our investigation, Law Engineering collected ground-water samples using the Hydropunch ground-water sampling system, utilizing the materials and installation procedures described in the CSA Workplan. We collected these ground-water samples at locations indicated on Drawing 4.4 to evaluate the lateral extent of ground-water contamination and to determine the optimal locations for the monitoring wells. This initial phase of investigation indicated

two areas of ground-water contamination, one near the Fuel Farm and one northeast of Building No. 480.

4.4.2 Monitoring-well Sampling Procedures

}

]

ľ

As stated in Section 3.4, Law Engineering installed 18 wells during the investigation to complement the seven installed during previous investigations. Prior to sampling each well, Law Engineering measured and recorded the depth to ground water using an electronic, water-level probe. We recorded the data collected and observations made on the Monitoring Well and Sampling Field Data Worksheets (Appendix I).

We evacuated all monitoring wells prior to collecting ground-water samples in order to remove stagnant water from the well casing and sand pack. We performed this task in an effort to collect samples representative of the water quality in the surficial aquifer. To evacuate the wells, we used decontaminated, Teflon bailers attached to new nylon cord. We measured and recorded specific conductance, pH, and water temperature throughout the evacuation process. We evacuated the wells of at least three standing well volumes and until indicator parameters had stabilized (or until the well exhibited dryness).

We collected ground-water samples from the 18 monitoring wells installed by Law Engineering, 17 of which were "paired" wells, and from the seven "single-cased" wells that had been installed during previous investigations. Prior to sampling the wells, Law Engineering personnel donned laboratory-grade gloves. We collected the water samples and immediately decanted the samples from the bailer into pre-labeled sample containers.

We sealed the containers, stored the containers in chilled coolers, and maintained custody of the samples until shipment at the end of each day. Chain-of-custody forms are included in Appendix J.

4.4.3 Results of the Ground-water Sampling

We have presented a summary of laboratory analyses of the ground-water samples from the Hydropunch sampling in Table 4.3. Reports of laboratory analyses are included in Appendix H. The ground-water samples were tested for purgeable aromatics by EPA Method 602, modified to include methyl tertiary butyl ether (MTBE).

We have presented isopleth maps for the combined total concentrations of benzene, toluene, ethylbenzene and total xylenes (BTEX) (Drawing 4.5) and for MTBE

concentrations (Drawing 4.6) documented in the Hydropunch ground-water samples. This map shows two plumes of contamination, one in the vicinity of the Fuel Farm and one extending from the area just north of Building No. 480 to the northeast. This preliminary identification of contaminant plumes allowed us to effectively place permanent monitoring wells.

J

1

We have presented a summary of laboratory analyses of the ground-water samples collected from the monitoring wells in Table 4.4 for the shallow screened intervals and in Table 4.5 for the deep screened intervals. The laboratory analyses are included in Appendix H. We tested these ground-water samples for purgeable halocarbons by EPA Method 601, for purgeable aromatics by EPA Method 602 modified to include MTBE, and for lead by EPA Method 7000. We also tested samples from four wells (MW-8S, MW-14S, MW-24S and MW-25S) for polynuclear aromatic hydrocarbons by EPA Method 610.

The laboratory results, when compared with the results of the soil analyses, show what appears to be at least two separate plumes of ground-water contamination. We have presented an isopleth map (Drawing 4.7) for the combined total concentrations of benzene, toluene, ethylbenzene and total xylenes (BTEX) in the shallow screened interval which shows these two plumes. We have presented a second isopleth map

(Drawing 4.8) for the combined total concentrations of BTEX in the deep screened interval. The isopleth map of the lower screened interval shows significantly lower levels of ground-water contamination, in the areas which generally correspond to the plumes observed in the shallow screened interval.

The first plume of the shallow screened interval is in the vicinity of the Fuel Farm. The ground water has been contaminated with hydrocarbons typically related to petroleum fuel including BTEX. The hydrocarbon contamination appears to be originating within the fuel storage and transmission area, in agreement with the results of the Tracer study, which indicated petroleum vapors beneath the Fuel Farm. Contaminants appear to be migrating to the northeast, the predominant direction of ground-water flow.

The second plume of the shallow screened interval is in the vicinity of the UST located behind Building No. 480 and extends to the northeast, towards the ponded stormwater. The ground water has been contaminated with BTEX and other petroleum-related constituents (heavier hydrocarbons) including fluorene, naphthalene, 1-methylnapthalene and 2-methylnapthalene.

Law Engineering has also identified three areas of ground water contaminated with chlorinated compounds from samples collected over the shallow screened interval. The first is in the vicinity of MW-10 and EMW-5, the second is in the vicinity of EMW-7 and MW-19 and the third is in the vicinity of MW-14 (Drawing 4.9). Laboratory analyses of the ground-water samples from these wells document contamination by trichloroethene and tetrachloroethane, constituents commonly found in solvents and degreasers.

i da likada

The source of contamination in MW-10 is apparently outside the study area and is unknown at this time. The contamination found in and downgradient of MW-14 may be related to the gasoline station formerly located adjacent to the ice house. Solvents and degreasers are commonly used at gasoline stations and maintenance facilities, and it is possible that the waste solvents from these sites were disposed of onto the ground. Over an extended period of time, continual disposal of these solvents in this manner could result in ground-water contamination.

Law Engineering could not identify a source of the chlorinated compounds detected in samples collected from EMW-7 and MW-19, although these compounds may be related to activities of the former automotive maintenance shop in Building No. TC-474, south of the study area. Law Engineering recommends identifying the source of this contamination.

Law Engineering also identified ground water contaminated with chlorinated compounds in the deep screened interval (Drawing 4.10). The areas of contamination generally correspond to those observed in the shallow screened intervals of wells.

Law Engineering cannot identify a consistent pattern of lead concentrations in either the shallow or deep screened intervals at the study area (Drawings 4.11 and 4.12). The well with the highest concentration of lead, EMW-5, is upgradient of known or suspected contaminant sources, while wells within the two contaminant plumes (for example, MW-20, MW-21, MW-22, MW-25) often exhibit relatively low levels of lead contamination. We also observed wells near the boundaries of the BTEX plumes with low levels of contamination (for example, MW-17, MW-23, MW-14) and levels of lead contamination similar to those wells with high levels of contamination. In summary, we are not able to draw any conclusions regarding the probable relationship between lead concentrations detected at the Fuel Farm and migration patterns of water-borne lead resulting from petroleum-fuel releases.

Law Engineering has documented concentrations of MTBE, an unleaded gasoline additive, below the state interim standard in five wells, four in the shallow screened interval (Drawing 4.13) and one (MW-18) in the deep screened interval. MTBE is highly soluble in water, and often is the first contaminant observed at the leading edge

Ł

of a plume. The levels of MTBE documented in EMW-6, MW-17 and MW-18, all of which are downgradient of the Fuel Farm, are likely the result of the leaking gasoline line referenced in Section 2.2.1. Law Engineering has not identified a likely source for the MTBE documented in MW-9.

1

Law Engineering documented ground water containing levels of chloroform in excess of the state ground-water quality standard in MW-14. Law Engineering collected a sample of the potable water at the base from the spigot adjacent to Building No. TC-364 and tested the sample for purgeable halocarbons and purgeable aromatic hydrocarbons. The laboratory analysis of this water sample (identified as "potable water" in Table 4.4) revealed concentrations of chloroform, bromoform, bromodichloromethane, and dibromochloromthane in excess of the laboratory detection limits and of state ground-water standards. These compounds may often be found in municipal water supplies as a result of the chlorination process.

In summary, Law Engineering has documented ground-water contamination both in the upper portion of the surficial aquifer and, to a lesser extent, at depths 10 to 15 feet below the water table. We have identified a confining layer within the surficial aquifer which may act as a barrier to the vertical migration of these contaminants.

The rate at which these contaminants migrate through the subsurface is affected by several geohydrochemical processes including molecular diffusion, mechanical mixing, sorption-desorption, ion-exchange, hydrolysis and biodegradation. Because the resources involved in attempting to model the effects of these processes at the project site are significant, we have chosen to apply a relatively simple analytical technique (USEPA, 1985b) with which to arrive at conservative (greater than anticipated) estimates of contaminant-migration rates at the study area. This analytical technique takes into account only sorption-desorption of the contaminant constituent (expressed in terms of the "retardation factor") and the average, linear velocity of ground-water flow at the site.

For purposes of these calculations, we selected an average linear velocity of ground-water flow of 1.33 feet/day (the mean value of those reported in Section 3.5). The resulting calculations, contained in Appendix K, show that the rate of benzene movement is estimated at 0.44 feet/day. By comparison, naphthalene (a relatively hydrophobic compound) is estimated to migrate at a rate of 0.029 feet/day. With the exception of MTBE, the migration rates of remaining organic constituents detected in the study area are likely to fall within the range bounded by benzene and naphthalene. Please note that these migration rates are only gross estimates which may vary considerably from actual field-migration rates.

5.0 PROCEDURES FOR QUALITY CONTROL

5.1 Decontamination of Equipment

The CSA Workplan details the quality-control procedures followed for handling and decontaminating equipment in the field. As outlined in the Workplan, we decontaminated our drilling equipment in an open area just south of Fourth Street, opposite the Fuel Farm.

5.2 Collection and Shipment of Samples

]

J

The CSA Workplan details the quality-control procedures followed for collecting, handling and shipping samples. We employed three quality-control measures to provide checks on the integrity and quality of our ground-water sampling program: rinse blanks, trip blanks and duplicate samples.

Law Engineering submitted equipment rinse blanks to the laboratory for evaluation of procedures which we used to decontaminate the Teflon bailers. Law Engineering also submitted trip blanks to the laboratory to check the integrity of the sample containers, to determine if contaminants may have entered the sample containers during shipment

to and from the job site, and to check for laboratory-induced contamination. Each of the blanks was analyzed for purgeable aromatics. The two rinse blanks and four trip blanks submitted with the Hydropunch ground-water samples did not contain contaminant levels above the laboratory detection limit. Six of the ten blanks submitted with the monitoring-well ground-water samples exhibited contamination with xylenes and, in one instance, MTBE in excess of, but near, the laboratory detection limits (Table 5.1).

Law Engineering collected two duplicate ground-water samples as a check on our sampling technique and on the reproducibility of laboratory-testing procedures. For this test, we collected a sample from MW-14S, which we labelled as MW-26S, and a sample from MW-24S, which we labelled as MW-27S. Laboratory analyses of these duplicates are included in Table 4.4.

Analysis of our procedures revealed that bailer decontamination was successful in eliminating the introduction of contaminants through the sampling equipment. Based on the relatively low concentrations of xylenes (2.0 ug/l) detected in the blanks, Law Engineering believes that no significant petroleum-hydrocarbon contamination of ground-water samples occurred as a result of contaminated sampling equipment.

5.3 Evaluation of Chemical Data

In order to assess the quality of laboratory-produced data, our laboratory performed an evaluation of the chemical data. This evaluation included reviews of surrogate failures, calibration verification, holding times, organic-blank contamination, documentation and sample condition. In summary, the evaluation results indicate that reported discrepancies between actual results/procedures and standard results/procedures are not considered to have major impact on the data reported. A copy of the analytical data review report is included in Appendix L.

6.0 SURVEY OF POTENTIAL RECEPTORS

Fuel contamination in any one of four physical states or "phases"' (residual, vapor, liquid, dissolved) may be transmitted to receptors through ingestion, inhalation, or absorption. As petroleum fuel seeps into the subsurface, it will undergo a transformation process that results in adsorption of hydrocarbons onto soil particles (residual phase) and release of volatile hydrocarbons into pore spaces (vapor phase). If any product remains after adsorption and volatilization take place, it will continue to move vertically downward (in the absence of preferred lateral routes of migration)

until reaching the capillary-fringe area or a relatively impermeable barrier if one is located above the capillary fringe. At this point, the fuel (liquid phase) will tend to spread throughout the capillary fringe and the transformation process will continue with the dissolution of hydrocarbons into ground water (dissolved phase). An evaluation of the relationship between contaminated media and exposure pathways at the project site is summarized in Table 6.1.

Receptors may be potentially exposed to the hydrocarbons found in the soil primarily through inhalation of volatilized compounds and dermal contact with soil at sites contaminated with hydrocarbons. However, based on headspace and laboratory tests results, petroleum contamination is not generally present in near-surface soil at the Fuel Farm. As indicated in Section 4.2, soil contamination is generally present only at depths below approximately 4 feet. As a result, exposure to these soils is contingent upon site disturbance through construction or remediation activities.

In the event that soil remediation is required, there may be some inhalation exposure from volatilization of the hydrocarbons found in the soil. Volatile components will be released and the potential for exposure will occur at this time. Dermal exposure from soil contact by personnel may also occur if remediation activities include excavation. Since this is an occupational exposure, the receptor analysis for these exposure pathways should be considered as part of the design plan for site remediation.

Exposure through ingestion most commonly occurs from consumption of drinking water obtained from contaminated wells or contaminated public-water supplies. The active water-supply wells at Camp Geiger supply water from the Castle Hayne aquifer and are located to the west of the Fuel Farm, upgradient of the documented contamination. Due to the presence of an apparent confining unit separating the contaminated surficial aquifer from the Castle Hayne, and the distance between the Fuel Farm and the supply wells, it is unlikely that contamination in the surficial aquifer at the Fuel Farm has affected the water-supply wells at Camp Geiger. The study by Harned et al (1989) did not include chemical testing of water samples from the water-supply wells.

Subsurface contaminants have been known to find their way into buried water-supply lines primarily through direct contact with free product. Law Engineering did not receive a complete set of site maps showing the locations of all the water lines in the study area. However, because free product was not observed in the study area, potential exposure to contaminants in this manner is unlikely.

ł

Law Engineering observed three access points to the subsurface. The first is the manway providing access to the sanitary sewer, which is located just southeast of the Fuel Farm. The second is the storm sewer and oil/water separator which collects

stormwater on the concrete pad adjacent to the ASTs. The third is a collapsing storm-sewer manway behind the former site of the filling station; due to its condition, this manway appeared inaccessible. Law Engineering performed a vapor-phase survey at these access points using the PID and did not detect volatile organics. Inspection of Building No. 480 revealed no means of access to the subsurface (manways, vaults, etc.) within the buildings. This was confirmed by Mr. Blake, who fills the UST behind this building and who is familiar with its design.

The results of the survey of potential receptors indicate that the presence of contaminants in the subsurface at the Fuel Farm does not constitute an imminent or near-future health threat to potential receptors. However, it is possible that organic vapors may be present along portions of subsurface utilities which may possibly result in exposure during maintenance and repair activities.

7.0 REMEDIAL ALTERNATIVES AND RECOMMENDATIONS

This discussion of remedial alternatives and preliminary recommendations is directed primarily toward the contamination by petroleum hydrocarbons encountered at the Camp Geiger Fuel Farm. However, these alternatives and recommendations may also be applicable to chlorinated hydrocarbon contamination.

Due to the spatial distribution of petroleum-hydrocarbon contamination in the soil (adsorbed phase) and water samples (dissolved phase) collected from the Fuel Farm, it appears that at least two separate releases of petroleum fuel have occurred at the project site. The first release occurred approximately four years ago from the gasoline line in the vicinity of the Fuel Farm. Contamination of the soil and ground-water remain in this area from this release. The second release, from the UST behind Building No. 480, may still be occurring and has resulted in soil and ground-water contamination. Therefore, as an initial step in the remedial process, we recommend thoroughly evaluating the integrity of this UST system.

7.1 <u>Soil Remediation</u>

7.1.1 Overview and Objectives of Soil Remediation

Protection of public health and ground-water quality are the primary reasons for soil remediation at sites involving leaking UST systems. As discussed in Section 6.0 of this report, the potential for exposure to contaminated soil at the Camp Geiger Fuel Farm is minimal as long as the subsurface remains undisturbed. However, guidelines for remediation of soil contaminated by petroleum have been established by the Groundwater Section of the Division of Environmental Management, DEHNR (1990).

## Notes:

- (1) No free product detected in surface waters; water supply wells draw from Castle Hayne aquifer.
- (2) Potential for exposure only if subsurface below 8 feet BLS is disturbed.
- (3) Through use of Camp Geiger water-supply wells for drinking, cooking, and bathing.
- (4) Ground-water sampling results indicate that plume does not extend to surface waters.
- (5) Potential for exposure during maintenance/repair work in subsurface utility confinements.

## UNDERGROUND STORAGE TANK (UST) SITE CHECK INVESTIGATION REPORT FORMER MESS HALL HEATING PLANT UST MARINE CORPS BASE CAMP GEIGER, NORTH CAROLINA ATEC PROJECT NUMBER: 26-07-92-00142

#### **1.0 INTRODUCTION**

ATEC Associates, Inc. was contracted to perform an underground storage tank (UST) Site Check of the Former Mess Hall Heating Plant UST located at the Camp Geiger area of Marine Corps Base (MCB), Camp Lejeune, North Carolina. Site Checks are to be conducted at various Marine facilities at UST locations where releases are suspected to have occurred. The Site Checks are needed to comply with both the U.S. Environmental Protection Agency (EPA) and North Carolina UST regulations. This investigation report details the work performed at the project site and the information obtained through this investigation.

The project site is located adjacent to Building TC-341 at Camp Geiger MCB (Figure 1). ATEC installed three wells around the Former Mess Hall Heating Plant UST. The three wells were installed under Well Construction Permit No. 66-0264-WM-0274, which was issued on May 20, 1992 by the State of North Carolina Department of Environment, Health, and Natural Resources (DEHNR). A copy of this permit and copies of the completed Well Construction Records are included in Appendix A.

The now abandoned UST was used to supply number six heating fuel to the boilers of an adjacent heating plant which is now demolished (Figure 2). The size and construction of the UST are unknown. The installation date of the tank is approximately 1941. A suspected release from the UST was documented by a subsurface investigation performed by Law Engineering in November of 1991. Laboratory analysis of a soil sample for Total Petroleum Hydrocarbons obtained adjacent to the UST quantified a contaminant level of 8400 ppm.

#### 2.0 SITE ASSESSMENT

To obtain the information necessary to describe and evaluate the project site geology and the extent of contamination, ATEC installed three groundwater monitoring wells and analyzed soil samples from the three well locations. Prior to the installation of the monitoring wells, the well locations were cleared for underground utilities by MCB personnel.

## 2.1 Area Geology

=

The project site is located within the Atlantic Coastal Plain physiographic province, which consists of a wedge of stratified, unconsolidated and semi-consolidated sediments that dip and thicken eastward. These sediments consist primarily of sand, clay, silt and gravel, with variable amounts of shell material, that range in age from Cretaceous to Recent (Holocene). Unconformably underlying the Coastal Plain sediments is a basement rock surface composed of massive igneous rocks and highly deformed metamorphic rocks that range in age from Precambrian to lower Paleozoic. The basement surface forms the basal limit of the Coastal Plain hydrogeologic system, which consists of a surficial, unconfined water table aquifer and seven deeper level confined to semi-confined aquifers separated by intervening aquitards (less permeable units) (Meng and Harsh, 1988; Hamilton and Larson, 1989).

Topographically, the project site is at an elevation of approximately 20 feet above mean sea level (USGS, 1971). Topographic relief across the site is relatively slight. Based on topographic map interpretation, surface drainage at the project site flows to the east, toward Brinson Creek, a tributary of the New River. However, human activities at the site, such as construction and grading may have affected the natural surface water drainage.

## 2.2 Soil Boring and Soil Sampling Program

On June 1 and 2, 1992, ATEC drilled three soil borings at the project site. These borings were converted to monitoring wells (Figure 2). The soil borings were advanced using a Mobil B-57 truck-mounted drill rig with 10-inch diameter hollow stem augers. The augers and sampling tools were decontaminated between borings using a pressure washer to minimize the potential of cross-contamination. During the soil boring activities, soil samples were collected with split spoon samplers at 0 to 2 feet, 2 to 4 feet, 4 to 6 feet, 8 to 10 feet, 13 to 15 feet, and 18 to 20 feet. Soils encountered at each of the well locations consisted of a surficial brown to gray silty sand to 4 feet below the ground surface (BGS), underlain by a brown to gray medium sand to 10 feet BGS. Greenish gray, fine to medium sands were encountered from 13 to 15 feet BGS, followed by greenish gray to gray medium sands from 18 to 20 feet. Soil boring logs are included in Appendix B.

Each split spoon sample was collected in a clean sample jar, leaving ample head space in the jar. The samples were then screened in the field for the presence of petroleum hydrocarbons with a Photoionization Detector (PID). The results of this screening yielded readings that ranged from 0 part per million (ppm) up to a maximum of 119 ppm at the MW-2 location.

A separate soil sample for laboratory analysis was collected from each boring at the approximate depth of the water table. A duplicate soil sample was taken at the MW-2 location and marked "MWS-4". These soil samples were analyzed in the laboratory for Total Petroleum Hydrocarbons (TPH) using EPA Method 8015 (California modified) and for Benzene, Toluene, Ethylbenzene, and Total Xylenes (BTEX) using EPA Method 8020. The limit set by the DEHNR is 10 ppm for TPH in soil. No limits are established for BTEX concentrations in soil. As shown in Table 1, the laboratory results indicate the presence of TPH contamination at all three well locations at levels above the DEHNR action level of 10 ppm (Figure 3).

#### Table 1: Laboratory Results of Soil Analyses

| Sample_No.                    | TPH 8015<br>mg/kg | BTEX<br>ug/kg                                                         |

Note: mg/kg is numerically equivalent to parts per million (ppm) ug/kg is numerically equivalent to parts per billion (ppb)

## 2.3 Monitoring Well Installation

On June 1 and 2, 1992, ATEC installed three groundwater monitoring wells at the project site. The monitoring well locations are shown in Figure 2. During the drilling activities, the water table was encountered at approximately 8 feet BGS.

The wells were constructed with 10 feet of 0.010 inch slotted schedule 40 polyvinyl chloride (PVC) screen and 10 feet of PVC riser. A Number 2 industrial sand was used to create a filter pack around the well casings to 2 feet above the well screen. A one foot thick annular seal of bentonite pellets was placed above the sand filter

pack and concrete grout was placed above the bentonite seal to the surface to protect the wells from infiltrating surface waters. Concrete pads, steel posts and protective covers were set above the wells to protect them from damage. A well identification tag, including construction data, was installed on each well. Well completion data is included with the soil boring logs in Appendix B.

## 2.4 Groundwater Sampling Program

The three groundwater monitoring wells were developed by pumping a minimum of five well bore volumes of groundwater to remove fine silt and clay particles present in the wells and to remove stagnant standing water. New development hose and sampling tubing was used for each well to minimize the potential for crosscontamination between wells. Prior to surveying each well, water levels were measured using an oil/water interface probe, which can detect the presence of free phase product. At the time of the survey, none of the monitoring wells contained free product.

The three wells were sampled on June 6, 1992. The static water table prior to purging was measured between 9.08 feet and 9.88 feet below the top of the well casings. The groundwater samples were collected at a depth of approximately one foot below the water table. A duplicate sample was obtained from MW-2 and labeled as "MW-4". No trip blanks were prepared. The water samples were analyzed in the laboratory for TPH using EPA Method 8015 (California modified) and for BTEX using EPA Method 8020. As shown in Table 2, the results of the TPH analyses for groundwater from the wells ranged from <1 ppm to 5 ppm. The DEHNR has not set limits for TPH in groundwater. Concentrations of the BTEX constituents also were detected in groundwater at MW-2 (Figure 4). Allowable levels of BTEX in groundwater are available in Subchapter 2L, Section 0.200 of the North Carolina Administrative Code, "Classifications and Water Quality Standards

Applicable to the Groundwaters of North Carolina" and are as follows: Benzene 0.001 ppm (1 parts per billion (ppb)), Toluene 1.0 ppm (1,000 ppb), Ethylbenzene 0.029 ppm (29 ppb), and Total Xylenes 0.4 ppm (400 ppb). The benzene limit was exceeded at MW-2.

Total Xylenes 5

## 2.5 Groundwater Flow Direction

Groundwater flow at the project site was expected to mimic the surface drainage pattern, with groundwater flowing to the east, toward Brinson Creek. A survey of the monitoring wells and groundwater level elevations was conducted to determine the actual direction of groundwater flow at the project site. The wells were surveyed for future reference - survey needs to be tied into established "permanent" benchmarks from the elevation of a fire hydrant (identification tag 6-16-6) located east of the site adjacent to a railroad spur, using mean sea level (MSL) as datum. Table 3 lists the measured elevations. Groundwater flow was determined to be toward the east, as shown in Figure 5.

## Table 3: Monitoring Well Elevations

Benchmark (Fire hydrant) Elevation = 18.08 feet above MSL

| Well<br><u>Number</u> | Casing<br>(feet MSL) | Elevation<br>Water Table (feet) | Water Table<br>Depth To Elevation<br>(feet MSL) |       |
|-----------------------|----------------------|---------------------------------|-------------------------------------------------|-------|

The velocity of groundwater flow at the project site was calculated to provide a general estimate of how rapidly groundwater, and any associated contamination, would migrate away from the USTs. The following standard equation based on Darcy's law of groundwater flow was used to estimate the groundwater velocity:

V = (K/n) (dh/dl);

where V = rate of groundwater flow (ft/day)

dh/dl = measured water table gradient (0.005 ft/ft)

K = assumed hydraulic conductivity (0.28 ft/day for fine sands)

n = assumed porosity factor (0.30)

The rate of groundwater flow in the water table aquifer was calculated using an assumed porosity of 30 percent, a measured water table gradient of 0.005 ft/ft, and an assumed hydraulic conductivity of 0.28 ft/day for a fine sand aquifer (Fetter, 1980). The calculated velocity is approximately 0.005 ft/day or 2 ft/year. This analysis shows that groundwater contamination would migrate away from the UST area toward the east. However, as an aquifer pumping or slug test was not conducted at this site, this calculated value represents only a rough estimate of the true groundwater flow velocity. This estimated velocity also does not necessarily correspond with the rate of contaminant movement, as contaminant characteristics greatly affect their rate of movement.

## 3.0 CONCLUSIONS AND RECOMMENDATIONS

The Former Mess Hall Heating Plant UST, which contained number six heating fuel, is located adjacent to Building TC-341. The UST was installed in the early 1940's. Based upon the information gathered during the UST Site Check, high levels of contamination caused by a suspected release of petroleum hydrocarbons from the UST are present at the site. This investigation revealed the presence of both soil and groundwater contamination around the UST.

ATEC recommends that the UST and its associated lines be removed as soon as possible due to the systems age, construction, and inactivity. If UST removal is conducted, soil samples from the UST excavation pit should be analyzed for petroleum hydrocarbon content. Once this investigation is completed, the need for further action can be assessed.

Law Engineering Job No. 475-09183-01

## EXECUTIVE SUMMARY

In accordance with the Naval Facilities Engineering Command Order for Supplies and Services Contract No. N62470-93-D-4020 dated August 29, 1993, Law Engineering preformed a Leaking Underground Storage Tank Comprehensive Site Assessment (CSA) in the vicinity of Heating Plant Building TC-341 at Camp Geiger within the Marine Corps Base (MCB) in Camp Lejeune, North Carolina. The investigation involved the assessment of soil and ground-water quality conditions in the vicinity of Building TC-341, near the former location of a number 6 heating oil underground storage tank (UST) of unknown size and the associated 6-inch diameter fuel supply line which originated at the Camp Geiger fuel farm located east of the site.

The assessment involved the installation of twelve Type II and two Type III monitoring wells and analysis of soil and ground-water samples. Soil samples were tested for total petroleum hydrocarbons (TPH) according to EPA preparation/testing Methods 5030/8015 (volatile fraction), 3550/8015 (semi-volatile fraction) and 9071 (oil and grease), as well as TCLP metals, flash point and pH. Ground-water samples were analyzed for purgeable aromatic hydrocarbons according to EPA Method 602, and polynuclear aromatic hydrocarbons according to EPA Method 610, and also for the eight RCRA metals.

Based upon the results of our investigation, petroleum related contamination is present within soils and ground water within the area of investigation. The majority of soil contamination appears to be located within the immediate vicinity of the underground storage tank (UST) system at the site. Ground-water contamination was detected mainly in the upper portion of the surficial aquifer. Free product is also present in the immediate vicinity of the UST system.

The extent of benzene, ethylbenzene, toluene, total xylenes, methyl-tertiary-butyl ether and polynuclear aromatic hydrocarbons within the shallow ground water has been adequately defined by the sampling network used in this study. Elevated concentrations of PAH compounds at the furthest downgradient well location suggest that other petroleum sources located east of TC-341 have contributed petroleum compounds to the shallow ground water in the area.

Results of this assessment suggest that the majority of soil and ground-water contamination originating from the tank system at Building TC-341 has been adequately defined for the purposes of preparing a Corrective Action Plan.

Based on our assessment of the subject site, soil and ground water both indicated the presence of compounds characteristic of fuel oil that leaked from the UST system at TC-341 and possibly gasoline or Jet fuel from the petroleum source located east of TC-341. The presence of free product in ground-water coupled with elevated concentrations of petroleum constituents requires additional measures to satisfy groundwater requirements set forth by the state.

Our recommendations are as follows:

- Initiate free product recovery activities in the vicinity of the TC-341 UST system.
- Provide a copy of this comprehensive site assessment to the State for their review and files.
- Perform additional investigation to determine the limits of soil and ground-water contamination to the east of Building TC-341.
- Begin preparation of a Corrective Action Plan.

### **1.0 INTRODUCTION**

### 1.1 <u>Purpose of Investigation</u>

The Commander of the Atlantic Division Naval Facilities Engineering Command in Norfolk, Virginia, contracted with Law Companies Group, Inc. to perform a Leaking Underground Storage Tank Comprehensive Site Assessment (CSA) at Building TC-341, located on Camp Geiger at the Marine Corps Base at Camp Lejeune, North Carolina (Drawing 1.1). The purpose of the investigation was to identify the presence, magnitude and extent of possible free product accumulation and around-water contamination, and assess potential exposure to subsurface contaminants resulting from the release of Number 6 heating oil from an underground storage tank (UST) system at the site. As stated in the Leaking Underground Storage Tank Workplan contained in Appendix A, the objective of the investigation was to provide sufficient data to meet the requirements of Sections 280.63 and 280.65 of 40 CFR Part 280, Federal Technical Standards for Underground Storage Tanks. This data should also be sufficient to meet the requirements of Sections .0704 and .0706 of Title 15A, Chapter 2, Subchapter 2N, North Carolina Criteria and Standards Applicable To Underground Storage Tanks and Comprehensive Site Assessments. This report is designed to include information requested by the North Carolina Department of Environment, Health and Natural Resources in accordance with the document entitled "Groundwater Section Guidelines For The Investigation and Remediation of Soils and Groundwater" dated March 1993 (Revised June 1993).

### 1.2 <u>Scope of Work</u>

Authorization to proceed with the investigation was granted by the Commander of the Atlantic Division Naval Facilities Engineering Command, Norfolk, Virginia, via Contract No. N62470-93-D-4020, Delivery Order No. 0001, dated October 29, 1993. As specified in the contract requirements and outlined in the delivery order, Law Engineering prepared a work plan and health and safety plan to outline a site specific scope of work for field assessment activities.

The investigation involved the advancement of fourteen soil borings from which soil samples were obtained and into which twelve Type II and two Type III monitoring wells were installed. The delivery order also included provisions to sample three of the previously installed Type II monitoring wells.

Soil and ground-water samples were collected from the soil borings and monitoring wells for both on-site and off-site laboratory analysis. The collected data were used to delineate the horizontal and vertical extent of soil and ground-water contamination and to identify potential receptors that could be affected by the release so that a Corrective Action Plan (CAP) for the site can be developed. The specific methods

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

employed during performance of the project activities and the results, conclusions and recommendations of the CSA are described within the appropriate sections of this report.

#### 1.3 Area of Investigation

The site is located east of D Street between Third Street and Fourth Streets at Camp Geiger, Camp Lejeune Marine Corps Base (MCB). The subject UST of this study is located approximately 90 feet west of Building TC-341 and 20 feet east of D Street. The exact location of the UST is not clearly marked or identified on base drawings but can reportedly be identified as a slight cresting of the ground surface. The topography in the vicinity of the site is relatively flat and is at an elevation of approximately 15 feet above mean sea level (msl). Most of the area is not serviced by storm sewers. Runoff generally travels by sheet flow before entering drainage ditches which discharge into Brinson Creek which is located approximately 1000 feet northeast of the site.

#### 2.0 SITE HISTORY AND SOURCE CHARACTERIZATION

2.1 Site History and Operations

Information concerning the history of the project site was provided by Ms. Deborah Pickett with the Installation/Restoration Division of the Environmental Department (EMD/IRD) at Camp Lejeune.

The UST at the subject site was used to supply number 6 heating oil to a former mess hall heating plant which has since been demolished. The UST was reportedly installed around 1941. An underground fuel distribution supply line formerly connected the UST to the Camp Geiger Fuel Farm, located east of the TC-341 site.

#### 2.2 <u>Contaminant Source Inventory</u>

Free product was observed in MW-1 and MW-2 (Drawing 2.1), which are located in close proximity to the UST and the fuel supply line. However, according to EMD/IRD it could not be determined whether the leak occurred from the UST or the associated

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

fuel supply line. Several building structures were once located east of the site which have since been demolished and include an ice house and a gasoline filling station. The Camp Geiger Fuel Farm also is located east of the site. Suspected or known areas of soil and ground-water contamination have been documented for these sites, all of which are located downgradient of the study area with respect to shallow ground-water flow direction and are not expected to affect the subject property.

#### 2.3 <u>Release Incident History</u>

A suspected release from the UST was first documented by Law Engineering, Inc. in September of 1991 during the investigation of the adjacent Camp Geiger Fuel Farm. The study identified the number 6 heating oil UST and associated piping as a potential source of contamination. One soil boring was advanced adjacent to the UST to provide a preliminary determination as to whether or not the tank had leaked. The analysis of two soil samples collected from the boring at 3.0 to 4.5 feet and 8.5 to 10.0 feet below land surface (BLS) (at ground water) detected total petroleum hydrocarbons (TPH) at 8,400 and 5,100 parts per million (ppm), respectively, by EPA preparation/testing Methods 3550/8015 and 5030/8015 (Law Engineering, 1991).

#### 2.4 <u>Previous Investigation</u>

Based upon the findings presented by Law Engineering, Inc. a three well site check was performed at the subject site by ATEC Associates, Inc. in June of 1992. Results of this work are presented in ATEC's report dated September 24, 1993. Each of the three Type II monitoring wells were installed to a depth of 20 feet BLS with 10 feet of 0.010-inch slotted polyvinyl chloride (PVC) screen and 10 feet to PVC riser. Ground water was measured between 9 and 10 feet BLS.

Headspace analysis of soil collected from the three monitor-well soil borings yielded readings ranging from 0 to 119 ppm. Analysis of three soil samples collected from the approximate depth of ground water from each of the three monitoring well borings indicated concentrations of TPH (EPA Method 8015) in each sample ranging from 110 to 2,000 ppm. Analysis of the soil samples for benzene, toluene, ethylbenzene, and xylenes (BTEX) detected total BTEX concentrations in soil samples from monitor-well soil boirngs MW-1 and MW-2 from 155 parts per billion (ppb) to 5,530 ppb, respectively (ATEC, 1992).

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

Ground-water samples were collected from each of the three monitoring wells and were also analyzed for BTEX. Analytical results indicated total BTEX concentrations of 34 ppb in MW-2. BTEX was not detected in ground-water samples collected from MW-1 and MW-3 (ATEC, 1992).

Ground-water was determined to flow to the east (ATEC, 1992). The rate of groundwater flow in the surficial aquifer was calculated by assuming a porosity of 30 percent, a measured water table gradient of 0.005 ft/ft, and an assumed hydraulic conductivity of 0.28 ft/day for a fine sand aquifer. Based upon this information, a ground-water flow velocity of 0.005 ft per day was calculated (ATEC, 1992).

#### 2.5 <u>History of Corrective Action</u>

The extent of corrective action has been the in-place abandonment of the UST and the associated fuel supply pipeline.

#### 3.0 MIGRATION PATHWAYS AND POTENTIAL RECEPTORS

#### 3.1 Water-Well Inventory

According to a map of the base water supply system provided by EMD/IRD at Camp LeJeune, the closest water supply well (T-15) appears to be located approximately 1000 feet to the northeast of the site. Other water supply wells located within a onehalf mile radius of the site include wells TC-104, TC-100, TC-202, TC-325, TC-502, NC-52, TC-600 and TC-700. The approximate locations of these wells with respect to Building TC-341 are shown on Drawing 3.1. All of these wells are located to the west of the site. These wells do not appear to be located hydraulically downgradient of the site. According to Mr. Tom Morris of EMD, all water derived from water supply wells in the Camp Geiger area is treated before use. Drinking water for all Camp Geiger residents is provided by the Camp Geiger main water-treatment plant located near the intersection of 6th Street and Church Street.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 3.2 <u>Utility Survey</u>

Subsurface utility trenches can often provide preferential pathways for migration of contaminants. Therefore, an attempt was made to identify and locate subsurface utilities in the vicinity of the site. Information on the location of utilities was provided by MCB Camp LeJeune Facilities Engineering in the form of plans and drawings. Additional information was obtained from interviews with personnel located at the subject site. Based on the information provided, utilities located within the project area include water and wastewater lines, and communication and electrical lines. The approximate locations of underground utility lines located proximal to the site are shown in Drawing 3.2 Typically, underground utilities are buried from 2 to 6 feet BLS. The presence of fill stone, sand or loosely consolidated soils around the below grade utilities could act as potential contaminant migration pathways.

#### 3.3 <u>Potential Receptor Survey</u>

#### **Biological Receptors**

Fuel contamination, in any one of four physical states or "phases"' (residual, vapor, liquid, dissolved), may be transmitted to receptors via ingestion, inhalation, or absorption. As petroleum fuel seeps through the subsurface, it will undergo a transformation process that results in adsorption of hydrocarbons onto soil particles (residual phase) and release of volatile hydrocarbons into pore spaces (vapor phase). If any product remains after adsorption and volatilization takes place, it will continue to move vertically downward (in the absence of preferred lateral routes of migration) until reaching the capillary fringe area or a relatively impermeable barrier if one is located above the capillary fringe. At this point, the fuel (liquid phase) will tend to spread throughout the capillary fringe and the transformation process will continue with the dissolution of hydrocarbons into ground water (dissolved phase). An evaluation of the relationship between contaminated media and exposure pathways at the project site is summarized in Table 3.1.

Receptors may be potentially exposed to the hydrocarbons found in the soil primarily through inhalation of volatilized compounds and dermal contact with soil at hydrocarbon contamination sites. Based on laboratory test results, petroleum contamination is present in near-surface soil at the project site. Exposure to these soils is contingent upon site disturbance via construction or remediation activities. In

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

the event that soil remediation is required, there may be some inhalation exposure from volatilization of the hydrocarbons found in the soil. Volatile components will be released and the potential for exposure will occur at this time. Dermal exposure from soil contact by personnel may also occur if remediation activities include excavation. Since this is an occupational exposure, the receptor analysis for these exposure pathways should be considered as part of the site remediation design plan.

Exposure via ingestion most commonly occurs from consumption of drinking water obtained from contaminated wells or contaminated public water supplies. According to our review of available information, the nearest operational water supply well is located approximately 1000 feet northeast of the project site. Since our assessment indicates that the direction of ground-water flow within the surficial aquifer is to the east, the potential for exposure to drinking-water wells from contamination originating from the subject site appears to be minimal.

#### Structural Receptors

Buildings in the vicinity of TC-341 appear to be slab-on-grade types of structures. A 6-inch water main line is located approximately 30 feet to the west of the UST and also approximately 300 feet east of the UST. Due to the close proximity of the water line to the west, and the line to the east being hydraulically down-gradient, they may be considered as possible receptors.

#### Hydrologic Receptors

The nearest surface water body to the site is Brinson Creek which is located approximately 1000 feet (0.4 miles) to the east-northeast. Marsh areas associated with Brinson Creek are located approximately 800 feet to the east-northeast of the site (USGS, 1971).

#### 4.0 SOILS INVESTIGATION

#### 4.1 <u>Site Topography</u>

The project area is at an elevation of approximately 16 to 17 feet above mean sea level (USGS, 1971). The project area is relatively flat, gently sloping to the east towards Brinson Creek. The area surrounding the tank system of TC-341 consists of

Draft Leaking Underground Storage Tank Site Assessment Report Building TC=341 MCB, Camp Lejeune, North Carolina

open, grassed area to the north, east and west, with Buildings TC-341 and TC-342 located south-southeast.

#### 4.2 <u>Regional Geology</u>

The study area is located within the Lower Coastal Plain Soil System (Wiscomico and Talbot System) and the Coastal Plain/Castle Hayne Limestone hydrologic area. The sediments of the Coastal Plain consist of interbedded sands, clays, calcareous clays, shell beds, sandstone, and limestone (LeGrand, 1959). These sediments are layered in interfingering beds and lenses that gently dip and thicken to the east and include ten aquifers and nine confining units. In the Camp LeJeune area, the sediments are about 1,500 feet thick and overlie igneous and metamorphic basement rocks. These sediments were deposited in marine or near-marine environments (Brown and others, 1972).

A brief summary of the geologic/hydrogeologic setting at the Building TC-341 site is provided in the CSA Workplan (Appendix A). In general, downward movement of ground water is obstructed by the presence of clay layers in Coastal Plain formations and consequently most of the ground-water recharge migrates laterally toward discharge areas through the surficial aquifer (Heath, 1980). Further details of regional geologic/hydrogeologic characteristics are provided in Section 5.1 of this report.

#### 4.3 Site Soils and Geology

Drilling, soil sampling and monitoring well installation activities were initiated and completed in March, 1994. Locations of these borings/wells, shown in Drawing 4.1, were located in the field based on analysis of previous studies of the site.

All drilling was accomplished using the hollow stem auger (HSA) technique (ASTM D-1452). Augers of 6.25-inch inner diameter (I.D.) were used to advance the boreholes. Prior to work, all down-hole drilling equipment was steam-cleaned. Soil cuttings were disposed of on-site in a roll-off box provided by Waste Industries, Inc. for off-site disposal. Soil samples were collected from each of the boreholes. Soil samples collected for classification during the drilling operation were generally obtained at depths of 0.0 to 1.5 feet, 3.5 to 5.0 feet, 8.5 to 10.0 feet and on 5-foot centers thereafter to boring termination. Boring depths ranged from 13.0 feet BLS for Type II monitoring wells, to 32 feet BLS for Type III monitoring wells. Soil samples

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

were collected with a 24 inch long, 1.375-inch I.D. (2-inch outer diameter) split spoon sampler. Split spoon sampling was performed in general accordance with ASTM D-1586 and the number of blows required to drive the sampler each six-inch increment was recorded on the field boring log. The soil samples were identified in the field using visual/manual techniques described in ASTM D-2487 and ASTM D-2488. The soil was classified in accordance with the Unified Soil Classification System and a record of each test boring was produced. The soil test boring records are presented in Appendix B. Representative portions of each sample were placed in pre-labeled plastic bags and sealed for subsequent headspace testing.

Near-surface soils within 6.0 to 11.0 feet BLS generally consist of fine silty sands with occasional clayey fine sands and fine sandy clay lenses. Beneath these surficial materials, soils generally consist of slightly silty to silty fine to coarse sands to a depth of approximately 32 feet. This type of deposit appears to comprise much of the surficial aquifer at the subject site. Soils classified in the field as gray slightly silty fine sand with generally lower penetration resistance were encountered at depths of approximately 13.5 to 15.0 feet in borings completed for both the Type II wells and Type III wells. Sampling was stopped at approximately 30 feet in borings for monitoring wells MW-9 and MW-15. Moist soil conditions were generally encountered at depths of approximately 4 to 6 feet BLS.

Two cross-sections, the locations of which are shown in Drawing 4.2, were developed for the site to present lithologic interpretations. The cross-sections, as developed from the boring records, are illustrated in Drawings 4.3 and 4.4.

Representative soil samples collected at depths of 8.5 to 10.0 feet and 20.0 to 21.5 feet BLS from MW-7 and MW-9, respectively, were submitted for laboratory grain-size distribution tests. The results of the grain-size distribution tests, presented in Appendix C, reveal that the samples collected from 8.5 to 10.0 feet contained 59.0% fine to medium sand and 41.0% silt and clay, and that the sample from 20.0 to 21.5 feet contained 85.5% sand, 14.2% silt and clay, and .3% gravel.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 4.4 Soil Contamination

The soil investigation activities were monitored with an HNu Photoionization Detector (PID) calibrated to 99.6 percent isobutylene, to determine the relative quantities of total volatile ionizable compounds in the borehole, in ambient air, and in the headspace of individual soil sample containers. Values recorded with the PID are qualitative only and are not directly comparable to actual laboratory analytical results. However, a PID is useful in providing a relative indication of the presence of total volatile ionizable compounds in soil samples.

Soil samples for headspace analysis were collected from each boring according to the following procedure:

- The decontaminated split-spoon sampler was driven to the desired depth interval.
- The split-spoon sampler was retrieved and immediately opened. A small portion of the sample was quickly removed from the split-spoon sampler and placed into a pre-labeled, airtight, plastic bag in a warm location. The remainder of the sample was placed in a second airtight, pre-labeled, laboratory container and stored on ice. Sample handling was executed carefully so as to minimize the loss of potential trace gases.
- At the conclusion of each sampling event, the headspace gas in the bags was measured for total ionizable compounds with the HNu, and the peak value was recorded for each bag sample.

Headspace sampling results are presented in Table 4.1. Results show elevated readings in soil samples collected from a depth of 3.5 to 15.0 feet BLS at location MW-14 and from a depth of 3.5 to 30.0 feet BLS at location MW-15. Results also show a slightly elevated reading in the 13.5 to 15.0 foot soil sample at location MW-16.

Two soil samples were retained from each soil boring for either on-site or off-site laboratory analysis. The on-site laboratory is owned and operated by Geochem Laboratories, Inc. of Morrisville, North Carolina. All off-site samples were submitted to Law Environmental National Laboratories in Pensacola, Florida. Approximately the

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

first fifty percent of soil samples collected from the monitoring well soil borings were packed on ice and submitted to the on-site lab to aid in locating the remaining borings. The remaining fifty percent of the soil samples were placed in a cooler, packed on ice and shipped to the off-site laboratory. The distribution of samples submitted to each respective laboratory is shown in Table 4.2. The soil samples submitted to both the on-site and off-site laboratories were analyzed for total petroleum hydrocarbons (TPH) according to EPA preparation/testing Methods 5030/8015 (volatile fraction), 3550/8015 (semi-volatile fraction) and 9071 (oil and grease). Selected soil samples were also analyzed for pH, flashpoint, TCLP metals and total lead. Custody of the samples was maintained by Law Engineering field staff until shipment or delivery to the on-site laboratory.

Chemical testing results for the soil samples collected are summarized in Table 4.3. The laboratory testing indicated the presence of detectable TPH-gasoline in soil samples collected at a depth of 3.5 to 5.0 feet at locations MW-14 and MW-15. The concentration of 4100 mg/Kg in MW-14 and 200 mg/Kg in MW-15 for TPH-gasoline at these locations is well above the State's action level of 10 mg/Kg. Laboratory testing also indicated the presence of detectable TPH-diesel in soil samples collected at a depth of 3.5 to 5.0 feet at locations MW-14 and MW-15. Concentration levels of 800 and 490 mg/Kg, which are above the State's action level of 40 mg/Kg for TPH-diesel, were detected respectively. Also, a concentration level of 11 of TPH diesel was detected in MW-11 and MW-17 at a depth of 0.0 to 1.5 feet. This level is below the State's action level of 40 mg/Kg. Drawing 4.5 shows the distribution of TPH results within the vadose zone soils at the site. Headspace analysis of soil samples analyzed by the on-site and off-site laboratories generally show a good correlation.

Laboratory testing indicated the presence of TCLP barium in soil samples collected from MW-11 and MW-14 at a depth of 3.5 to 5.0 feet at a concentration of 400 ug/L and 250 ug/L respectively, which are below the State's action level of 100,000 ug/L.

Laboratory results indicate that the pH of site soils falls generally in a range between 5.53 to 7.48 suggesting that the soils are slightly acidic to near neutral. TCLP metals barium, chromium, and cadmium were detected in two samples at concentrations below TCLP limits for the respective metals. Results of flashpoint analyses suggest that site soils are not flammable.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 5.0 GROUND-WATER INVESTIGATION

#### 5.1 <u>Regional Hydrogeology</u>

In the Camp Lejeune area, sediments deposited in marine or near-marine environments are about 1,500 feet thick and overlie igneous and metamorphic basement rocks. The aquifers of the Camp Lejeune area are the surficial, Castle Hayne, Beaufort, Peedee, Black Creek, and upper and lower Cape Fear aquifers. They are separated by less permeable clay and silt beds (confining units) that serve to impede the flow of ground water between the aquifers (Harned, 1989).

The surficial aquifer is a series of sediments, primarily sand and clay, which commonly extend to depths of 50 to 100 feet. This unit is not used for water supply on the Base. The principal water-supply aquifer for the Base is the series of sand and limestone beds that occur between 50 and 300 feet below land surface. This series of sediments generally is known as the Castle Hayne aquifer. The Castle Hayne aquifer is about 150 to 350 feet thick in the area and is the most productive aquifer in North Carolina. It is a critical water-supply source, not only for Camp Lejeune but also for the southern coast and east-central Coastal Plain of North Carolina (Harned, 1989).

Camp Lejeune is situated in an area where the Castle Hayne aquifer contains freshwater, although the proximity of saltwater in deeper layers just below the aquifer and in the New River estuary is of concern in managing water withdrawals from the aquifer. The aquifers that lie below the Castle Hayne consist of a thick sequence of sand and clay. Although some of these aquifers are used for water supply elsewhere in the Coastal Plain, they contain saltwater in the Camp Lejeune area (Harned, 1989).

Water levels in wells tapping the surficial aquifer vary seasonally. The surficial aquifer receives more recharge in the winter than in the summer when much of the water evaporates or is transpired by plants before it can reach the water table. Therefore, the water table generally is highest in the winter months and lowest in summer or early fall. The hydraulic head in a confined aquifer, such as the Castle Hayne, shows a different pattern of variation over time than that in an unconfined aquifer. Some seasonal variation also is common in the water levels of the Castle Hayne aquifer, but the changes tend to be slower and over a smaller range than for water-table wells (Harned, 1989).

Draft Leaking Underground Storage Tank Site Assessment Report Building TC=341 MCB, Camp Lejeune, North Carolina

#### 5.2 <u>Site Hydrogeology</u>

Site specific data used to characterize the local hydrogeology was obtained through the installation of ground-water monitoring wells. A total of twelve Type II and two Type III ground-water monitoring wells were constructed during this investigation utilizing the materials and installation procedures described in the Workplan (Appendix A). These specifications included decontamination of the drilling equipment and well construction materials with a pressure steam cleaning unit. All monitoring well heads are protected by concrete pads and well head covers. Monitoring well installation details for the Type II and Type III wells are included in Appendix D.

Depths to ground water were measured in all monitoring wells on March 30, 1994. The measurements are included on the Monitoring Well Casing and Water Elevation Worksheets contained in Appendix E. Elevations of the monitoring wells installed by Law Engineering were determined by McKim and Creed Engineers and are also included in the Worksheets contained in Appendix E.

Based on measured ground-water elevations in the monitoring wells, a water-table elevation contour map was constructed to determine ground-water flow direction as shown in Drawing 5.1. A horizontal hydraulic gradient of approximately 0.006 within the surficial aquifer was determined from this map (see Appendix F). In general, ground-water within the surficial aquifer flows to the east toward Brinson Creek, which discharges into the New River. The stabilized ground-water table at the time of our field work appears to have been between 10.50 feet and 13.50 feet BLS within the area of investigation. The average hydraulic conductivity of the surficial aquifer as determined through recovery tests is estimated to be approximately 1.5 feet per day (see Appendix G).

As indicated by a comparison of water-level elevations in the following paired Type II and Type III monitoring wells: MW-9 (screened from 27.0 to 32.0 feet BLS) and MW-10 (screened from 3.0 to 13.0 feet BLS); MW-14 (screened from 3.0 to 13.0 feet BLS) and MW-15 (screened from 25.0 to 30.0 feet BLS); the direction of ground water flow within the surficial aquifer appears have a slight downward component in the vicinity of both pairs locations.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 5.3 Extent of Free Product

In conformance with regulations promulgated by the North Carolina Department of Environment, Health and Natural Resources, the estimated extent of free product was delineated for the site. Free product is defined as a regulated substance that is present as a non-aqueous phase liquid (e.g., liquid not dissolved in water).

Type II monitoring wells were constructed to allow for detection of free product in the surficial aquifer. As indicated on the Monitoring Well Casing and Water Elevation Worksheet presented in Appendix E, free product thicknesses were measured in two on-site wells during this investigation. Free product was detected in monitoring wells MW-1 and MW-2, which were installed prior to this investigation. The estimated extent of free product is shown in Drawing 5.2.

#### 5.4 Dissolved Ground-Water Contamination

Ground-water samples were collected from each of the fourteen newly installed monitoring wells. Prior to sampling, personnel donned laboratory grade gloves. These gloves were replaced after sampling each well to minimize the potential for cross-contamination. Prior to well sampling, the depths to ground water were determined using an electronic water-level meter. The distance from the measuring point to each respective depth was measured and recorded. The data collected and observations made were recorded on the Monitoring Well and Sampling Field Data Worksheets (Appendix H).

Approximate volumes of water removed during development and observations of turbidity are listed in Table 5.1. The development water, approximately 166 gallons total, was temporarily containerized on-site and then taken off-site to P & W Oil Company, Inc. in Leland, North Carolina.

All monitoring wells were purged prior to sample collection to remove stagnant water from the well casing and sand pack in an effort to collect samples representative of the water quality in the surficial aquifer. Each well was purged using a pre-cleaned teflon bailer. Specific conductance, pH, and water temperature were measured and recorded throughout the purging process. Well purging continued until three standing well volumes were removed and indicator parameters had stabilized. Water samples were then collected and immediately decanted gently from the bailer into pre-labeled

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

sample containers. These containers were sealed, and stored in chilled coolers. Custody of the samples was maintained by Law Engineering field staff until samples were relinquished for laboratory analysis. Water generated during the well purging and development process was temporarily containerized on-site and then disposed of at an off-site disposal facility.

Ground-water samples were analyzed for purgeable aromatic hydrocarbons according to EPA Method 602 for monitoring wells MW-1, MW-4, MW-7, MW-8 and MW-10. Samples from the monitoring wells were submitted to both the on-site and off-site laboratories for analysis. Table 5.2 shows the distribution of samples submitted to each of the laboratories. A summary of ground-water analytical results is presented in Table 5.3. Results suggest that dissolved phase purgeable aromatic hydrocarbons are present in the upper portion of the surficial aquifer.

The concentrations of constituents detected within shallow ground water were plotted on site maps to illustrate their spatial distribution in the vicinity of the site. Maps showing the extent of free product detected and concentrations of benzene, toluene, ethylbenzene, total xylenes, methyl-tertiary-butyl ether (MTBE), and total polynuclear aromatic hydrocarbon (PAH) compounds are presented in Drawings 5.2 through 5.8 respectively. Drawings 5.2, 5.3, 5.4, 5.5, 5.6 and 5.7 illustrate that the horizontal and vertical extent of free product, benzene, toluene, ethylbenzene, total xylenes and MTBE has been defined by the sampling network. Similarly, Drawing 5.8 suggests that the horizontal and vertical extent of total PAH compounds within shallow ground water in the vicinity of the subject UST has also been defined adequately by the network.

The distribution of of PAH compounds in groundwater shown in Drawing 5.8 illustrates that the extent of PAH contamination has been defined to the north, south and west of the subject tank system, and to levels of 10's of a ug/l, 300 feet downgradient of that tank system.

Laboratory testing of the ground-water sample collected from MW-14 indicates the presence of total PAH compounds at a concentration of 5240 ug/L. MW-14 is located approximately 350 feet east of the leaking UST. Concentrations of only 14.6 ug/L were detected in MW-8. In light of these data and the fact that other potential contaminant sources have been identified downgradient of the subject site, it does not appear that the contamination found in MW-14 is solely a result of the TC-341 UST.

14

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 5.5 <u>Vertical Gradient Determinations</u>

Ground water exhibits both horizontal and vertical components of flow within an aquifer. The hydraulic gradient is the difference in hydraulic head along a flow path divided by the distance between those points. The vertical component of the gradient may be either upward or downward within the aquifer. At the project site there are two well clusters which pair a shallow Type II monitoring well with a deeper Type III monitoring well. These well clusters are identified below:

| Shallow Well | Deep Well |  |
|--------------|-----------|--|
| MW-10        | MW-9      |  |
| MW-14        | MW-15     |  |

The vertical gradient is calculated by first determining the difference in the static water level elevations at each well. Second, the relative elevation of the middle of the screened interval is determined for each well. Finally, the difference in the static water-level elevations is divided by the difference in the midscreen elevations. This value is arbitrarily assigned a positive value if the ground water is moving vertically downward and a negative value if the ground water is moving vertically upward. Vertical gradients determined for the site and values used to calculate the gradient are summarized in Table 5.4. According the these data, the vertical gradient at both locations is downward.

#### 5.6 Rate of Contaminant Migration

The rate at which contaminants migrate through the subsurface is affected by several geohydrochemical processes including molecular diffusion, mechanical mixing, sorption-desorption, ion-exchange, hydrolysis and biodegradation. Because the resources involved in attempting to model the effects of these processes at the project site are significant, we have chosen to apply a relatively simple analytical technique (USEPA, 1985) with which to arrive at a conservative (greater than anticipated) estimate of contaminant migration rates at the site. The analytical technique takes into account only sorption-desorption of the contaminant constituent (expressed in terms of the "retardation factor") and the average linear ground-water flow velocity at the site.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

For purposes of these calculations, we used the average hydraulic conductivity of the surficial aquifer as determined by on-site recovery tests (1.5 feet/day), and the horizontal hydraulic gradient determined to be approximately 0.006. If an effective porosity of 20% is assumed for the surficial aquifer, a seepage velocity of approximately 0.05 feet per day can be determined using Darcy's Law. The approximate rates of movement for petroleum compounds detected within the surficial aquifer would likely be slower than the ground-water seepage rate due to reasons discussed previously. Below is the expected range of contaminant movement rates at the site.

| Benzo(a)anthracene | 10 <sup>-5</sup>   |
|--------------------|--------------------|
| МТВЕ               | 0.04               |
| COMPOUND           | RATE Vc (Feet/Day) |

It is important to note that these migration rates are only gross estimates and may vary considerably from actual field migration rates.

#### 6.0 QUALITY CONTROL PROCEDURES

#### 6.1 Equipment Decontamination

Quality control procedures for equipment handling and decontamination are detailed in the Workplan (Appendix A). Decontamination of the drilling equipment was performed at the wash rack located at Building FC200 and Building TC-341, where waste soil and water were collected and containerized on-site for subsequent proper disposal.

#### 6.2 Sample Collection and Shipment

Details of quality control procedures for sample collection, handling and shipment are included in the CSA Workplan (Appendix A). To provide checks on the integrity and quality of the field sampling program performed at the project site, two quality control measures were employed. First, equipment rinse blanks were submitted to the laboratory for evaluation of procedures used to decontaminate the Teflon sampling

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

bailers. Second, trip blanks were submitted to the laboratory during shipment of the monitoring well samples to perform checks on the integrity of the sample containers and ascertain whether contaminants may have entered the samples during transport to and from the job site. Laboratory quality controls included the use of lab blanks throughout the analytical procedures to check for laboratory induced contamination.

Analysis of the rinse blank collected during the monitoring-well sampling for polynuclear aromatic hydrocarbon compounds did exhibit the presence of such compounds in excess of the laboratory detection limits. This result appears to be inconsequential however, because three of the five detected compounds were not detected in any other samples. Further, the two that were detected in samples from monitoring wells were one to two orders of magnitude greater in concentration than those detected in the rinse blank. It is likely that the rinse blank sample was contaminated by an external source during collection. Duplicate sample analysis produced results that were generally consistent.

#### 7.0 CONCLUSIONS AND RECOMMENDATIONS

Based upon our assessment activities at the site, a spatial distribution of petroleumhydrocarbon contamination at levels exceeding regulatory standards exists within ground water at the site. Preliminary recommendations describe additional activities that will be needed to meet remaining regulatory requirements.

#### 7.1 Overview and Objectives of Soil and Ground-water Remediation

7.1.1 Soil

Results of this investigation indicate that the extent of vadose soil contamination has been defined and occurs within the immediate vicinity of the tank. Protection of public health and ground-water quality are the primary reasons for soil remediation at sites with elevated concentrations of TPH. As discussed in Section 3.0 of this report, the potential for exposure to contaminated soil at the project site is minimal as long as the subsurface remains undisturbed. However, guidelines for remediation of soil contaminated by petroleum have been established by the Groundwater Section of the Division of Environmental Management, DEHNR (1993).

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

Within these guidelines, the Groundwater Section has set "action levels" of 10 mg/Kg for soils contaminated with low boiling point hydrocarbons and 40 mg/Kg for soils contaminated with medium boiling point hydrocarbons in contact with ground water. Where petroleum contaminated soil is not in contact with the shallow ground water and other, specific conditions apply, the final clean-up levels for site soils may range up to 300 mg/Kg and 1200 mg/Kg for low and medium boiling point hydrocarbons respectively. Because free product is present on the water table in the vicinity of the UST system, and because TPH was not detected in unsaturated soils at the remaining boring/monitoring well locations, completion of a Site Sensitivity Evaluation was not required. Therefore, the objectives for remediation of contaminated soil at the project site should focus on 1) eliminating the adsorbed hydrocarbons as an ongoing source of ground-water contamination through leaching and desorption and 2) complying with NCDEHNR guidelines which require remediation of all soil containing petroleum hydrocarbons in excess of DEM action levels.

#### 7.1.2 Ground Water

The results of this investigation indicate that ground water flows primarily to the east and that contamination has occurred in mainly the upper portion of the surficial aquifer.

The necessity of remediation efforts designed to restore ground-water quality is often not easily quantified. The decision ultimately rests upon regulatory requirements, the measured and/or perceived present and future utility of the ground-water resource, the risks associated with the potential exposure to the contaminants, and the availability of resources with which to implement and operate a ground-water restoration project. Obviously, remediation is warranted in a situation where the risk to public health or welfare is unavoidable and unacceptable as a result of exposure to ground-water contaminants. As indicated in Section 3.0 and Table 3.1 of this report, present exposure to ground-water contaminants in the vicinity of the project site is considered unlikely.

With respect to regulatory requirements, the North Carolina Environmental Management Commission (EMC) has adopted maximum allowable concentrations for contaminant constituents in ground water. The maximum regulatory concentration for compounds detected in ground water beneath the site are included in Table 5.3. For compounds which do not have a numerical standard, a petition may be filed with

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

the North Carolina Division of Environmental Management (DEM) in order to establish such a standard. Otherwise, a maximum allowable concentration for the compound not listed is equal to its laboratory detection limit. As indicted in Table 5.3, Law Engineering has documented the occurrence of several constituents at levels which exceed the maximum allowable concentrations for at the project site.

At sites where ground-water standards have been exceeded, rules adopted by the EMC and enforced by DEM require that a corrective action plan for the restoration of ground-water quality be prepared. The feasibility and justification for alternative remedial options ranging from natural attenuation (no action) to active remediation are addressed in the corrective action plan with the addition of limited confirmation sampling. This comprehensive site assessment will provide the data needed for preparation of such a plan.

#### 7.2 <u>Conclusions</u>

Based upon the results of our investigation, petroleum related contamination is present within soils and ground water within the area of investigation. The majority of soil contamination appears to occur within the immediate vicinity of the UST subject system. Ground-water contamination was detected primarily in the upper portion of the surficial aquifer.

The extent of benzene, ethylbenzene, toluene, total xylenes, methyl-tertiary-butyl ether and polynuclear aromatic hydrocarbons within site ground water has been adequately defined by the sampling network used in this study. Elevated concentrations of PAH compounds at the furthest downgradient well location suggest that other petroleum sources located east of TC-341 have contributed petroleum compounds to the shallow ground water in that area.

Results of this assessment suggest that the majority of soil and ground-water contamination originating from the tank system at Building TC-341 has been adequately defined for the purposes of preparing a Corrective Action Plan.

Draft Leaking Underground Storage Tank Site Assessment Report Building TC-341 MCB, Camp Lejeune, North Carolina

#### 7.3 <u>Recommendations</u>

Based on our assessment of the subject site, soil and ground water both indicated the presence of compounds characteristic of fuel oil that leaked from the UST system at TC-341 and possibly gasoline or Jet fuel from the petroleum source located east of TC-341. The presence of free product in ground-water coupled with elevated concentrations of petroleum constituents requires additional measures to satisfy groundwater requirements set forth by the state.

Our recommendations are as follows:

- Initiate free product recovery activities in the vicinity of the TC-341 UST system.
- Provide a copy of this comprehensive site assessment to the State for their review and files.
- Perform additional investigation to determine the limits of soil and ground-water contamination to the east of Building TC-341.
- Begin preparation of a Corrective Action Plan.

NOTES:

NA Not Applicable

(1) Free product detected in surficial waters; water supply wells draw from Castle Hayne aquifer.

(2) Potential for exposure only if subsurface below approximately 1.0 foot BLS is disturbed.

(3) Via use of MCAS water supply lines that extend through the project area for drinking, cooking and bathing.

(4) Preliminary ground-water sampling results indicated that petroleum constituents may extend to Brinson Creek that may carry constituents to the New River.

(5) Limited assessment indicates sunsurface vaults, manways, or other exposure routes in vicinity of known soil/product contamination.

#### All results are ug/l

Shaded Area = Concentrations detected above NC groundwater standards

Maximum detection limit is equal to laboratory detection limit

\*\* Split Sample; 610 analysis for sample done by both on-site and off-site laboratories

ND Not Detected; see laboratory reports for applicable detection limits

-- Sample not analyzed for this parameter

NA Not Analyzed: MTBE is not included in on-site laboratory EPA 602 analysis

NOTES:

<sup>1</sup> Indicates existing well depth

All results are ug/i

Shaded Area = Concentrations detected above NC groundwater standards

٠ Maximun detection limit is equal to laboratory detection limit

\*\* Split Sample; 610 analysis for sample done by both on-site and off-site laboratories
 Not Detected; see laboratory reports for applicable detection limits
 Sample not analyzed for this parameter
 NA Not Analyzed; MTBE is not included in on-site laboratory EPA 602 analysis

NOTES:

<sup>1</sup> Indicates existing well depth

All results are ug/l

Shaded Area = Concentrations detected above NC groundwater standards

\* Maximun detection limit is equal to laboratory detection limit

\*\* Split Sample; 610 analysis for sample done by both on-site and off-site laboratories

ND Not Detected; see laboratory reports for applicable detection limits

-- Sample not analyzed for this parameter

NA Not Analyzed; MTBE is not included in on-site laboratory EPA 602 analysis

# 1.0 CAMP GEIGER AREA FUEL FARM SITE INVESTIGATION

Tracer Research Corporation (Tracer Research) performed a shallow soil gas and groundwater investigation at the Camp Geiger Area Fuel Farm, Camp Geiger, Jacksonville, North Carolina. The investigation was conducted April 13 through 16, 1994 for Baker Environmental of Coraopolis, Pennsylvania.

### 1.1 Objective

The purpose of the investigation was to evaluate and delineate possible subsurface contamination by screening shallow soil gas and groundwater for the presence of volatile organic compounds (VOCs). Soil gas and groundwater samples were collected and analyzed for the following analyte classes and compounds:

Analyte Class: Hydrocarbon: benzene

Analyte Class: Halocarbon: trichloroethene (TCE)

## 1.2 Overview of Results

For this investigation, sixty-seven soil gas and seventy-two groundwater samples were collected from seventy-three sample locations. Soil gas samples were collected at 2 to 7 feet below ground surface (bgs). Groundwater samples were collected at 1 to 10 feet bgs. A summary of the results of the soil gas and groundwater investigation is presented in Table 1 and Table 2 on the following page.

| Compound | # of samples in<br>which compound<br>was detected | Low<br>conc.<br>µg/L | High<br>conc.<br>µg/L | Sample(s)<br>with<br>high conc. |
|----------|---------------------------------------------------|----------------------|-----------------------|---------------------------------|
| Benzene  | 11                                                | 0.01                 | 2                     | 35-SG61-4'                      |

#### 2.0 SITE DESCRIPTION

The investigation was conducted near various buildings and along Brinson Creek at the Camp Geiger Area Fuel Farm. Samples were collected through asphalt and grass cover.

The subsurface of the site was characterized by sand and silt. Groundwater was reported to be approximately 6 to 8 feet bgs. The direction of groundwater flow was not reported.

#### 3.0 SOIL GAS SAMPLING PROCEDURES

Soil gas sampling probes consisted of 7-foot lengths of 3/4-inch diameter hollow steel pipe. The probes were fitted with detachable drive tips and hydraulically pushed and/or pounded to a depth of 2 to 7 feet bgs. An electric rotary hammer was used to drill through the asphalt.

The aboveground end of each probe was fitted with an aluminum reducer (manifold) and a length of polyethylene tubing leading to a vacuum pump. Soil gas was pulled by the vacuum pump into the probe. Samples were collected in a glass syringe by inserting a syringe needle through a silicone rubber segment in the evacuation line and down into the steel probe. The vacuum was monitored by a vacuum gauge to ensure an adequate gas flow from the vadose zone was maintained.

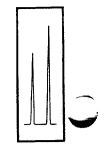

The volume of air within the probe was purged by evacuating 2 to 5 probe volumes of gas. The evacuation time in minutes versus the vacuum in inches of mercury (Hg) was used to calculate the necessary evacuation time. The vacuum in inches Hg was recorded at each sampling location. Probe vacuums ranged from 2 to 12 inches Hg. The maximum capacity of the pump was approximately 22 inches Hg.

## 4.0 GROUNDWATER SAMPLING PROCEDURES

When groundwater was encountered, water samples were collected. Sampling probes consisted of 7- to 14-foot lengths of 3/4-inch diameter hollow steel pipe. Groundwater samples were collected at 1 to 10 feet bgs. The hollow probes with detachable drive points were advanced below the water table. Once at the desired depth, the probes were withdrawn several inches to permit water to flow into the resulting hole. The aboveground end of the sampling probes were fitted with a vacuum adaptor (metal reducer) and a length of polyethylene tubing leading to a vacuum pump. A vacuum of up to 22 inches Hg was applied to the interior of the probe for 10 to 15 minutes or until water was drawn up the probe. The water accumulated in the hole was removed by vacuum through a 1/4-inch polyethylene tube inserted down into the probe to the bottom of the hole. Because the water is induced to flow into a very narrow hole, it can be sampled with little exposure to air and, consequently, the loss of volatile compounds by evaporation is reduced. The polyethylene tubing was used only once and discarded to avoid cross contamination.

Groundwater samples were collected in 40 milliliter (mL) VOA vials that were filled to exclude air and capped with Teflon-lined septa caps. Approximately half of the liquid in the bottle was decanted, the vials were shaken vigorously, and a sample of the headspace from the container was injected into the gas chromatograph (GC).

Indirect (headspace) analysis is the preferred technique when a large number of water samples are to be performed daily. The method is more time efficient for the measurement of volatile organics than direct injection of the water sample into the GC because there is less chance of semi-volatile and non-volatile organics contaminating the system. Depending upon the partitioning coefficient of a given compound, the

indirect analysis method may be more sensitive than the direct injection method. The precision and accuracy of both methods are similar.

#### 5.0 ANALYTICAL PARAMETERS

Up to 10 mL of soil gas and 40 mL of groundwater were collected for immediate analyses in the Tracer Research analytical van. Analytical instruments were calibrated daily using fresh working standards made from National Institute of Sciences and Technology traceable standards and reagent blanked solvents.

The GC was calibrated for indirect analysis by decanting 20 mL of the known standard, leaving approximately the same amount of headspace as in the water headspace samples. The standard bottle was resealed and shaken vigorously for 30 seconds. An analysis of the headspace in the bottle determined the Response Factor (RF) which was then used to calculate the sample concentrations.

#### 5.1 Chromatographic System

A Hewlett Packard 5890 Series II gas chromatograph, equipped with a flame ionization detector (FID), electron capture detector (ECD) and two computing integrators, was used for the soil gas and groundwater headspace analyses. Compounds were separated on two 6 foot by 1/8 inch OD packed analytical column (10% OV101 stationary phase bonded to 80/100 mesh Chromosorb W support) in a temperature controlled oven. Benzene was detected on the FID and TCE was detected on the ECD. Nitrogen was used as the carrier gas. The following paragraphs explain the GC, FID, and ECD processes.

#### **GC Process**

The soil gas and groundwater headspace vapor is injected into the GC where it is swept through the analytical column by the carrier gas. The detector senses the presence of a component different from the carrier gas and converts that information to an electrical signal. The components of the sample pass through the column at different rates, according to their individual properties, and are detected by the detector. Compounds are identified by the time it takes them to pass through the column (retention time).

### FID Process

The FID utilizes a flame produced by the combustion of hydrogen and air. When a component, which has been separated on the GC analytical column, is introduced into the flame, a large increase in ions occurs. A collector with a polarizing voltage is applied near the flame and the ions are attracted and produce a current, which is proportional to the amount of the sample compound in the flame. The electrical current causes the computing integrator to record a peak on a chromatogram. By measuring the area of the peak and comparing that area to the integrator response of a known aqueous standard, the concentration of the analyte in the sample is determined.

#### **ECD** Process

The ECD captures low energy thermal electrons that have been ionized by beta particles. The flow of these captured electrons into an electrode produces a small current, which is collected and measured. When the halogen atoms (halocarbons) are introduced into the detector, electrons that would otherwise be collected at the electrode are captured by the sample, resulting in decreased current. The current causes the computing integrator to record a peak on a chromatogram. The area of the peak is compared to the peak generated by a known standard to determine the concentration of the analyte.

### 5.2 Analyses

Subsamples (replicate injections) of each soil gas and groundwater headspace sample were injected into the GC in volumes of 1 to 1,000 microliters ( $\mu$ L). The detection limits for target compounds depend on the sensitivity of the detector to the individual compound as well as the volume of the injection. The detection limits of the target compounds were calculated from the response factor, the sample size, and the calculated minimum peak size (area) observed under the conditions of the analyses. If any compound was not detected in an analysis, the detection limit is given as a "less than" value, e.g., <0.1  $\mu$ g/L. The following table presents the approximate detection limits of the soil gas and groundwater targeted compounds.

| Compound | Detection Lir | Detection Limits (µg/L)     |  |  |  |  |
|----------|---------------|-----------------------------|--|--|--|--|
| Benzene  | 0.01 sg       | 0.06 gr. water              |  |  |  |  |
| TCE      | 0.00009 sg    | 0.00009 sg 0.0004 gr. water |  |  |  |  |

#### 6.0 QUALITY ASSURANCE AND QUALITY CONTROL

Tracer Research's Quality Assurance (QA) and Quality Control (QC) program was followed to maintain data that was reproducible through the investigation. An overview presenting the significant aspects of this program is presented below.

#### Soil Gas/Groundwater Sampling Quality Assurance

To ensure consistent collection of samples, the following procedures are performed.

#### - Sampling Manifolds

Tracer Research's custom designed sampling manifold connects the sample probe to the vacuum line and pump. The manifold is designed to eliminate sample exposure to the polymeric (plastic) materials that connect the probe to the vacuum pump.

The sampling manifold is attached to the end of the probe, forming an air tight union between the probe and the silicone tubing septum. The septum connects the manifold to the pump vacuum line and permits syringe sampling.

This sampling system allows the sample to be taken upstream of the sampling pump, manifold, and septum. Since cross contamination of sampling equipment can be a major problem, Tracer Research replaces the materials (probe and syringe), between sampling points, that contact the soil gas before or during sampling.

#### -Sampling Probes

Steel probes are used only once each day. To eliminate the possibility of cross contamination, they are washed with high pressure soap and hot water spray, or steam-cleaned. Enough sampling probes are carried on each van to avoid the need to re-use any during the day.

#### -Glass Syringes

Glass syringes are used for only one sample a day and are washed and baked out at night. If they must be used twice, they are purged with carrier gas (nitrogen) and baked out between probe samplings.

#### - Polyethylene Tubing and VOA Vials

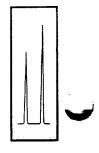

Polyethylene tubing and VOA vials used for the collection of groundwater samples are used only once and then discarded to avoid cross contamination.

#### -Sampling Efficiency

Soil gas/groundwater pumping is monitored by a vacuum gauge to ensure that an adequate flow of gas from the soil is maintained. A reliable gas sample can be obtained if the sample vacuum gauge reading is at least 2 inches Hg less than the maximum measured vacuum of the vacuum pump.

#### Analytical Quality Assurance Samples

Quality assurance samples are performed at the listed, or greater, frequencies in Table 4. The frequency depends on the number of samples analyzed and the length of time of the survey.

| Sample type                  | Frequency                           |
|------------------------------|-------------------------------------|
| Ambient Air Samples          | 3 per day or 1 per site             |
| Analytical Method Blanks     | 5% (1 per 20 samples or 1 a day)    |
| Continuing Calibration Check | 20% (1 every 5 samples)             |
| Field System Blank           | 10% (1 every 10 samples or 1 a day) |
| Reagent Blank                | 1 per set of working standards      |
| Replicate Samples            | 10 to 100% of samples collected     |

#### Table 4. Quality Assurance Samples

The ambient air samples are obtained on site by sampling the air immediately outside the mobile analytical van and directly injecting it into the GC. Analytical method blanks are taken to demonstrate that the analytical instrumentation is not contaminated. These are performed by injecting carrier gas (nitrogen) into the GC with the sampling syringe. Subsampling syringes are also checked in this fashion.

The injector port septa through which samples are injected into the GC are replaced daily to prevent possible gas leaks from the chromatographic column. All sampling and subsampling syringes are decontaminated after use and are not used again until they have been decontaminated by washing in anionic detergent and baking at 90°C.

Continuing calibration checks are analyzed to verify the detector response for the target VOCs. If the response changes by more than 25 percent, the gas chromatograph is recalibrated and new response factors are calculated.

Field system blanks are analyzed to check for contamination of the sampling apparatus, e.g., probe and sampling syringe. A sample is collected using standard soil gas sampling procedures, but without putting the probe into the ground. The results are compared to those obtained from a concurrently sampled ambient air analysis.

If the blanks detect compounds of interest at concentrations that indicate equipment contamination or concentrations that exceed normal background levels (ambient air analysis), corrective actions are performed. If the problem cannot be corrected, an out-of-control event is documented and reported.

A reagent blank is performed to ensure the solvent used to dilute the stock standards is not contaminated. Analytical instruments are calibrated daily using fresh working standards made from National Institute of Sciences and Technology (NIST) traceable standards and reagent blanked solvents.

Quantitative precision is assured by replicating analysis of 10 to 100 percent of the samples. The percentage is based upon sample analysis time. Replicate analyses are performed by subsampling vapors from the original syringe and VOA.

#### 7.0 RESULTS

The analytical results from this soil gas and groundwater investigation are condensed in Appendix A. The data are presented by location and by analyte concentration. When the compound was not detected, the detection limit is presented as a "less than" value, e.g.,  $<0.1 \mu g/L$ .

Samples are identified by sample type, sample location, and sampling depth. For example, 35-SG46-7' represents a soil gas sample collected from location 46 at a depth of 7 feet bgs. Sample 35-SGW56-10' represents a groundwater sample collected from location 56 at a depth of 10 feet bgs.
